In the tropical moth *Omphisa fuscidentalis*, larvae enter diapause at a time after the cessation of feeding, but before gut purge, i.e., probably at the wandering stage. Larval diapause lasts for 9 months, during which the secretory activity of prothoracic glands is detectable (Singtripop *et al*., 1999, 2000). Nevertheless, the hemolymph ecdysteroid titer remains at low levels (less than 10 ng ml^{-1}) in the first half of the diapause period, indicating that there is no feedback activation in spite of the satisfaction of a circumstantial requirement, i.e., low secretory activity of the glands and low ecdysteroid titer driving positive feedback. Topical application of JHA (methoprene) to those larvae breaks the diapause with associated increases in ecdysteroid titer and prothoracic gland secretory activity. This activation by JHA is also seen in larvae whose brains have been removed prior to JHA treatment, indicating that JHA does not stimulate brain PTTH release. Transplantation of the prothoracic glands of JHA-treated larvae to nontreated larvae breaks the diapause of the recipients. Successive transplantation after JHA treatment showed that JHA stimulation for only 1 day was enough to stimulate the prothoracic glands (Singtripop and Sakurai, unpublished data), but gland activity began to increase only 7 days after JHA treatment (Singtripop *et al*., 2000). What occurred in the glands during the 6 days immediately after JHA stimulation? During the diapause period, the prothoracic glands do not respond to either circulating ecdysteroids or the application of exogenous 20E (Singtripop *et al*., 2002). Second, JHA may not stimulate the glands directly. Thus, an assumption can be made that the glands are suppressed to respond to feedback activation by ecdysteroids, and JH may release the glands from such suppression. Such glands are capable of responding to ecdysteroids very gradually because the initial ecdysteroid titer is fairly low. This seems to account for the above-mentioned disagreement of *in vivo* and *in vitro* results for the effects of JHA on prothoracic glands in the prepupal period in *Manduca* and *Mamestra*. JH may act on prothoracic glands as a modulator of feedback activation in the wandering stage and the following prepupal period, and therefore JH application restores the increase of hemolymph ecdysteroid titer in the neck ligated larvae but cannot stimulate the glands *in vitro*.

In the last larval instar before the onset of wandering, prothoracic glands are suppressed by JH, but there have been no *in vitro* data, except for experiment using *Drosophila* ring glands (Richard and Gilbert, 1991). Both juvenile hormone bisepoxide (JHB_3), a *Drosophila* JH, and JH III well inhibit the ring glands, but the effective concentration is in the mM range, a rather pharmacological concentration. Application of hydroprene, an effective JH analog in *Manduca*, to larvae before the onset of wandering inhibits the increase in the hemolymph ecdysteroids that normally occurs with wandering, and the prothoracic gland activity as well (Rountree and Bollenbacher, 1986; Sakurai, 1990). In *Bombyx* feeding larvae, JHA application on day 3 of the fifth instar induces dauer larvae although the prothoracic glands after JHA treatment exhibit a low, but significant secretory activity that remains at low levels for as long as the larvae survive. By contrast, the gland activity in larvae whose brains have been removed increases autonomously after the operation to a degree sufficient to induce pupation (Sakurai and Imokawa, 1988). This indicates that JHA applied on day 3 might suppress the glands ability to respond to feedback activation, in addition to disturbing the PTTH secretion program of the brain discussed below (see Section 3.8.6.3). Thus, the switchover of the JH effects on prothoracic glands, occurring around the time of wandering, does not mean the switching from direct suppression to activation by JH. Rather, it may be caused by a change in the gland's responsiveness to feedback regulation. After wandering, JH supports feedback activation and/or interferes with feedback inhibition, although JH may directly suppress the glands before wandering, if the ecdysteroid titer is low.

There is no information at the molecular level on the effects of JH on prothoracic glands although JH modulates the 20E-inducible EcR and USP gene expressions in the *Manduca* epidermis (Hiruma *et al*., 1999). In day 2 fourth instar larval epidermis, USP-1 is downregulated by 20E, while USP-2 is upregulated. Coexistence of JH I with 20E suppresses the downregulation of USP-1 expression, indicating that JH may act antagonistically against 20E. USP is suggested to bind JH and act as a JH nuclear receptor (Jones and Sharp, 1997; Jones *et al*., 2001) (see **Chapter 3.7**), although the binding affinity of JH to USP is very low, and therefore USP is not yet accepted as a true JH nuclear receptor. JH is reported to activate EcR-dependent transcription in Chinese hamster ovary cells (Henrich *et al*., 2003). 20E activated the reporter gene expression in Chinese hamster ovary cells transfected with plasmids carrying a *Drosophila* EcR gene, a USP

gene, and an ecdysteroid-inducible reporter gene with five ecdysone response elements. In this system, the additional presence of JH III enhanced the response. The effective concentration of JH III was 40 μM (10 600 ng ml^{-1}), which is much higher than the JH concentration in larval hemolymph so far reported as less than 10 ng ml^{-1}, and thus the effect of JH III is only pharmacological. Accordingly, it is not known for sure if JH interacts directly with the EcR/USP heterodimer *in situ* to modulate the function of 20E-EcR/USP, but those reports indicate that JH is at least capable of binding to EcR/USP. If this is the case in the prothoracic glands, then JH may modulate the action of 20E by binding to USP-2 and reducing the feedback inhibition by 20E-EcR/USP-2, at least, in the prepupal period when the 20E titer is high enough to induce the complementary expressions of USP-1 and USP-2. If so, the delay in pupation caused by removal of corpora allata at the wandering stage could be interpreted as implying that JH in the prepupal period suppresses the feedback inhibition by suppressing the USP-2 expression by 20E, so that the glands secrete ecdysteroids until the peak titer. In the absence of JH, ecdysteroidogenesis is suppressed by 20E, resulting in an ecdysteroid titer that does not increase. The result is a delay in pupation. This interpretation of JH interaction with USP appears to account well for the fact that the USP-2 upregulation in *Manduca* prothoracic glands occurs only 1 day before the peak in ecdysteroid titer. In the prepupal period, the threshold concentration of 20E needed to induce USP-2 in the presence of JH may be higher than that in the absence of JH, and it is therefore of interest to examine the effects of JH on USP gene expression in the prothoracic glands.

3.8.6.3. Growth-Blocking Peptide–Corpora Allata–Prothoracic Gland Pathway

Endocrine control of larval growth could be more complicated than previously considered. There is another factor, besides PTTH, 20E and JH, that is indirectly involved in the control of ecdysteroidogenesis. The factor is growth-blocking peptide (GBP), an insect cytokine, which was first identified from the hemolymph of lepidopteran larvae that had been parasitized by a wasp (Hayakawa, 1991). When last (sixth) instar larvae of the armyworm *Pseudaletia separata* were parasitized by the parasitoid wasp *Cotesia kariyai*, larval growth was delayed so that the parasitoid wasp larvae had sufficient time to complete larval growth inside the host larvae and escape from them in order to pupate. The GBP concentration in the hemolymph is high in the penultimate instar and gradually declines early in the last larval instar. During normal growth, JH esterase in the hemolymph increases in early last instar larvae (Sparks *et al.*, 1983; Baker *et al.*, 1987), and the GBP concentration decreases concomitantly with the increase in esterase activity (Ohnishi *et al.*, 1995). GBP is produced by the larval fat body and acts to suppress JH esterase gene expression. Accordingly, suppression of GBP expression results in increased esterase activity, leading to a decline in JH concentration in the hemolymph. In the parasitized larvae, the GBP gene is activated by parasitization, and the elevated GBP suppresses the decline of JH titer by repressing the JH esterase gene (Hayakawa, 1990), which causes the hemolymph JH titer to remain high and thereby suppress the reactivation of the prothoracic glands. Thus, the parasite delays the growth of the host larvae. GBP also acts on epidermal cells by upregulating the DDC gene, resulting in an enhanced production of dopamine (Noguchi and Hayakawa, 1996; Noguchi *et al.*, 2003). Dopamine is released into the hemolymph and acts to enhance JH secretion from the corpora allata in early last instar larvae (Granger *et al.*, 1996) (see **Chapter 3.7**). These all figure in the sequential control of prothoracic gland activity (**Figure 1**). In the early last larval instar, the GBP gene is downregulated, although the mechanism is not known, resulting in a decrease in hemolymph GBP concentration. This decrease causes a downregulation of the DDC gene and results in a low dopamine concentration in the hemolymph. Although dopamine may not be the sole factor to maintain activity in the corpora allata, nevertheless, this activity may decline due to a low dopamine concentration. Simultaneously, JH esterase activity increases and as a result, the JH titer declines sharply, although it remains to be seen whether dopamine acts directly to suppress esterase gene expression or if the decreasing GBP titer directly elicits the upregulation of the JH esterase gene in the fat body. In addition to the GBP pathway, 20E is known to maintain or even stimulate the JH synthetic activity of the corpora allata (Whisenton *et al.*, 1987a, 1987b; Gu and Chow, 1996). Accordingly, the extremely low ecdysteroid titer in the early fifth instar (Bollenbacher *et al.*, 1981; Sakurai *et al.*, 1998) also contributes to the decrease in activity in the corpora allata. Finally, the declining JH titer releases the prothoracic glands from their suppression by JH and allows them to begin ecdysteroidogenesis, as well as to respond to PTTH (Sakurai *et al.*, 1989a). Because GBP is tightly involved in the changes in JH titer, the GBP–JH–prothoracic gland axis could be of importance in the control of prothoracic gland activity and therefore in

the hormonal control of insect growth and development. Since the parasitization of *P. separata* by the parasitoid *A. kariyai* appears to affect the host brain in a manner to suppress the PTTH release (Tanaka *et al.*, 1987), GBP could be affecting the brain PTTH cells.

There are conditions other than parasitization that delay larval growth, including low temperature (Malá *et al.*, 1987; Ohnishi *et al.*, 1995), insufficient food supply (Bounhiol, 1938; Nijhout and Williams, 1974a; Morita and Tojo, 1985; Miner *et al.*, 2000), and injury (O'Farrell *et al.*, 1960; Kunkel, 1977; Malá *et al.*, 1987). When last instar *P. separata* larvae are transferred from 25 to 10 °C, pupation is delayed by 11 days, and after the transfer, the GBP concentration is elevated and maintained at high levels for a certain period (Ohnishi *et al.*, 1995), indicating that the cold-stress suppressed, or even upregulated, the GBP gene in the fat body, which probably led to the delayed activation of prothoracic glands through a suppression of the decline of JH titer. Chilling of last instar *G. mellonella* larvae elicits an extra larval molt or a delay of pupation (Malá *et al.*, 1987). It is of interest that GBP is involved in the delay of larval growth under certain stressed circumstances. In the starved larvae, the feedback regulation of prothoracic gland activity seems to be more complicated. Starvation in last instar larvae of *Manduca* results in the maintainance of a high level of hemolymph JH, rather than the decline observed in normal feeding larvae (Cymborowski *et al.*, 1982), apparently due to the suppression of the decline in hemolymph JH esterase activity. Thus, the resulting high JH level may modulate the brain–prothoracic gland axis as mentioned above. This could be accounted for by the suppression of GBP expression that normally ceases after the last larval molt. However, suppression of larval growth by starvation is not simply caused by the suppression of prothoracic gland activity. Starvation suppresses the release of growth factors, like bombyxin and IDGFs, which are needed for normal growth. Nevertheless, 20E is required simultaneously to sustain larval growth (Nijhout and Grunert, 2002). Accordingly, the horizontal regulation of prothoracic glands appears to participate in helping the animal survive unexpectedly severe circumstances.

For more than four decades, injury has been recognized to delay larval growth, known as the injury effect. Following an operation such as the sham operation for allatectomy or autotomy of larval legs, the larval or even pupal period is usually prolonged by one or more days over that of intact animals. Similar sham operations on the last instar larvae of *G. mellonella* either prolongs the intermolt periods or produces supernumerary larvae. The injury is supposed to stimulate JH production (Malá *et al.*, 1987). In the sixth instar larvae of the cockroach *Blatta orientalis*, autotomy results in a delay of ecdysis by 4 days and also delays the appearance of the hemolymph ecdysteroid peak by 4 days (Kunkel, 1977), indicating that injury alters the ecdysone secretion program by affecting the brain–prothoracic gland axis. These two results are well explained by the operation of the GBP pathway (**Figure 1**). Injury elicits an increase in GBP titer, which stimulates the corpora allata to produce JH and also suppresses JH esterase expression, resulting in a high JH titer. The high titer suppresses the brain–prothoracic gland axis, delaying the appearance of the peak ecdysteroid titer. As a result, injury either delays ecdysis or induces supernumerary larvae. Thus, it seems highly possible that the humoral factor induced by injury is GBP, and that the GBP system is the cause for the delay in development.

3.8.7. Role of Feedback Regulation in Larval Growth and Metamorphosis: Meaning of the Shapes of the Ecdysteroid Peak

In contrast to the pupal (pharate adult) stage, during which the prothoracic glands degenerate and are unable to produce additional ecdysone, at the end of every larval stage including the last larval instar, gland activity decreases to a very low level. However, the degree of inactivation achieved is different at the end of each of at least the third, fourth, and fifth (last) instars of *Manduca* (Bollenbacher *et al.*, 1987; Smith and Pasquarello, 1989; Rybczynski and Gilbert, 1994; Smith, 1995) and *Bombyx* (Okuda *et al.*, 1985; Sakurai *et al.*, 1989b; Gu *et al.*, 1996, 2000; Takaki and Sakurai, 2003). Therefore, the mode of feedback inhibition of prothoracic glands may change developmentally.

When the ecdysteroid titer peaks occurring at the end of the third, fourth, and fifth larval instars and pupal stage are compared to each other, it is easily recognized that the peak titer, as well as its width, are developmental stage specific in *Manduca* (Bollenbacher *et al.*, 1981) and *Bombyx* (Kiguchi and Agui, 1981; Mizoguchi *et al.*, 2001; Takaki and Sakurai, 2003). In *Bombyx*, the peak width at the point of 50% peak height in the third, fourth, and fifth instars and pupal stage are 7 h (peak value of 1.2 μM), 9 h (1 μM), 18 h (3.2 μM), and 24 h (15.4 μM), respectively. The duration of the period with the titer above 1×10^{-7} M, a value similar to the binding affinity of 20E for the EcR/USP heterodimer, is 18 h, 32 h, 3 days, and 6

days, respectively (estimated from Takaki and Sakurai (2003) for the third and fourth instars, and from Mizoguchi *et al*. (2001) for the fifth instar and pupal periods). Thus, the shape of the ecdysteroid titer peak prior to the stationary molt in the third and fourth instars is sharper and narrower than those in the prepupal and pupal period. At the pupal molt the peak value is threefold higher than that for the stationary molt. This value in the pupal period is fivefold higher than that in the prepupal period. This is also the case in *Manduca* (Bollenbacher *et al*., 1981, 1987; Warren and Gilbert, 1986). Although little attention has been focused on such differences so far, these changes must possess an important meaning in the control of insect growth and metamorphosis.

In *Bombyx*, the composition of hemolymph ecdysteroids is strikingly different at the peak titers occurring between the fourth instar and prepupal period (Kamimura and Kiuchi, 2002). At day 2.5, 0.5 days prior to the peak in hemolymph ecdysteroids occurring in the fourth instar that lasts 4.5 days, the 20E concentration is fivefold higher than that of ecdysone, while at the peak, the 20E titer is 17 times as great as that of ecdysone. In contrast, 0.5 days prior to the peak titer in the prepupal period, ecdysone is the predominant ecdysteroid, as the 20E concentration is approximately 70% that of ecdysone. 20E becomes predominant by the time of the peak titer, although 20E concentrations are only 30% higher than ecdysone. In addition, the absolute concentrations of 20E at peak titer are 620 $ng\,ml^{-1}$ (1.3 μM) in the fourth instar and 480 $ng\,ml^{-1}$ (1 μM) in the fifth instar. In *Manduca* prothoracic glands of day 5 fifth instar larvae, 1 μM 20E significantly suppresses USP-1 while at the same time it stimulates USP-2 expression (Song and Gilbert, 1998). The fourth instar glands are also inhibited by 20E *in vitro*, similar to those of the fifth instar (Sakurai and Gilbert, unpublished data). These composite data from *Manduca* and *Bombyx* indicate that in the fourth instar, 20-monooxygenase activity sharply increases when prothoracic gland activity increases, and therefore secreted ecdysone is promptly converted to 20E, which provides for an acute induction of USP-2 and thereby elicits a strong negative feedback along with the increased sensitivity of the glands to 20E (Takaki and Sakurai, 2003). By contrast, in the prepupal period, 20-monooxygenase activity may only gradually increase, while the degree of feedback inhibition is not so strong as compared with that in the fourth instar. While receiving a weak feedback inhibition by 20E in the early period of feedback inhibition, the prothoracic glands are capable of responding to PTTH in the presence of 20E (Sakurai and Williams, 1989; Song and Gilbert, 1998), and therefore the glands may be able to respond to PTTH and secrete ecdysone even in the face of the feedback inhibition that occurs before the peak titer in the prepupal period.

The degree of sharpness of both the increase and decrease in the titer cannot be accounted for only by feedforward (PTTH) and feedback factors. As discussed elsewhere in this volume (see **Chapters 3.2, 3.3**, and **3.7**) and above, various factors are involved in the control of prothoracic gland secretory activity resulting in both upregulation and downregulation (**Figure 1**). JH acts as a modulator in a stage-specific manner. Nerves from the prothoracic ganglion suppress gland activity in at least some insects (Okajima and Kumagai, 1989; Richter and Böhm, 1997). Decreases in the titer also depend on ecdysteroid metabolism, starting with the conversion of ecdysone to 20E by the 20-monooxygenase followed by 26-hydroxylation mediated by the 26-hydroxylase that is induced by 20E (Hoffman *et al*., 1974; Williams *et al*., 1997). Thus, the stage-specific expression of these enzymes is also tightly involved in the decrease in the ecdysteroid titer.

The peak value, composition of ecdysteroids, and duration of ecdysteroid titer above a certain concentration are controlled precisely in a stage-specific manner, but the overall output of the gland is dominant and governs every aspect, directly or indirectly, of insect postembryonic development. Ecdysone has been regarded as an inactive prohormone because its affinity to EcR/USP is far less than that of 20E (Minakuchi *et al*., 2003). This low affinity well accounts for its very low biological activity measured using an *in vitro* system (Cherbas *et al*., 1980) where exogenous 20-monooxygenase activity is not a factor. A hormonal role for ecdysone is still conjectural, but one has been suggested over the last three decades (Mandaron, 1973; Tanaka and Takeda, 1993; Tanaka and Naya, 1995; Gilbert *et al*., 1996; Kamimura and Kiuchi, 2002). Nevertheless, 20E must be the main feedback factor in the brain–prothoracic gland axis.

3.8.8. Future Directions

In the study of feedback regulation of the endocrine system, one of the advantages of insects over mammals is that the regulation of most endocrine systems is tightly associated with embryonic and postembryonic development, including growth, pupal–adult differentiation, and cell death. In vertebrates, although hormonal regulation is seen in embryonic development, feedback and feedforward regulation

in the endocrine system is focused to a great extent on the adult stage and therefore the regulation is rather stereotypic. In insects, all the cells of the body are targets of two hormones, 20E and JH, regardless of their developmental stages. The regulation of prothoracic gland ecdysteroidogenesis is believed to be under the control of a complicated regulatory network. The regulatory mechanism of prothoracic gland activity includes almost every aspect found in a mammalian system, i.e., involving tropic and static factors, as well as a horizontal network of the control, neural control, and feedback regulation. At the cellular level, those factors may act through signal transducing pathways mediated by second messengers, a variety of kinases, and different combinations of transcription factors, including the nuclear receptors, EcRs and USPs, and their coactivators. All these factors could be involved in the regulation of gene expression, protein synthesis, and the transport of steroid intermediates in the prothoracic gland cells. As a result of the integration of all of those regulatory pathways, ecdysone secretion is either stimulated or suppressed. With the recent advances of analytical equipment and techniques, macrolepidopteran prothoracic glands (*Manduca*) are sufficiently large in mass to perform biochemical and pharmacological analysis of the aforementioned complicated regulation. However, *Drosophila* is different from other insects; for example, the involvement of JH in the stationary molt is not understood. Nevertheless, precocious metamorphosis can be induced by genetic manipulation (Bialecki *et al*., 2002), indicating that there should be a control mechanism to ensure the stationary molt. The most sophisticated genetic manipulation is available in *Drosophila*, which will be of great help in understanding the complicated feedback regulation systems in the endocrine systems of insects.

3.9 Hormonal Control of Reproductive Processes

A S Raikhel, University of California, Riverside, CA, USA
M R Brown, University of Georgia, Athens, GA, USA
X Belles, Institut de Biologia Molecular de Barcelona (CSIC), Spain

3.9.1. Introduction

The years following the 1985 publication of *Comprehensive Insect Physiology, Biochemistry and Pharmacology* have been marked by stunning developments in insect science. A technological revolution in biochemistry, molecular biology, and genetics has swept all areas of biological science, and has profoundly influenced insect science as well. With this technological revolution, the small size of insects is no longer a barrier to discovering their biochemical make-up, cloning or characterizing genes, or uncovering genetic and hormonal signals governing their functions. Sequencing of insect genomes, particularly that of *Drosophila melanogaster*, has led to the identification of previously unknown genes and to the development of functional genomic approaches that lead to further elucidation of genetic regulatory networks.

During this period, insect endocrinology has shifted its focus from physiology and biochemistry to molecular biology and genetics. The latter are the subjects of the present volume. This chapter specifically reviews the progress that has been achieved since 1985 in our understanding of the hormonal control of insect reproduction. Particular attention is paid to those areas where significant progress has been made at the molecular and genetic levels.

There are a number of recent reviews on hormonal regulation of yolk protein (*yp*) genes (Raikhel *et al*., 2003; Belles, 2004; Bownes, 2004; Wang *et al*., 2004); vitellogenins and their processing (Sappington *et al*., 2002; Telfer, 2002; Tufail *et al*., 2004); nonvitellogenin yolk proteins (Bownes and Pathirana, 2002; Telfer, 2002; Masuda *et al*., 2004; Yamahama *et al*., 2004), and the cell biology of the insect fat body (Giorgi *et al*., 2004).

3.9.2. Endocrine Control of Female Reproduction

3.9.2.1. Evolution of Endocrine Control of Vitellogenesis and Egg Development

The insect female reproductive system consists of the ovaries, which contain ovarioles, oviducts, spermatheca, accessory glands, vagina, and ovipositor (Davey, 1985; Chapman, 1998). Ovarioles are the egg producing units in the ovary. Typically, the insect ovary has four to ten ovarioles; however, some species contain many more ovarioles. Ovarioles are tubular and consist of both somatic and germline cells. At the apex of each ovariole, a germarium houses the primary germline cells. The follicles or egg chambers form within the germarium

and continue to mature along the ovariole tube. There are three types of ovaries in insects (Büning, 1994). Ovaries of primitive groups of insects contain panoistic ovarioles with egg chambers consisting of the oocytes surrounded by the follicular epithelium (panoistic ovarioles). In more advanced insects, where the structure of ovarioles is more complex (meroistic), some germ cells are set aside to form nurse cells that produce massive amounts of numerous products for the developing oocyte. In polytrophic meroistic ovarioles, each egg chamber contains its own group of nurse cells connected to the oocyte. Follicle cells surround the oocyte and nurse cells. In telotrophic meroistic ovaries, each ovariole contains the trophic chamber with large groups of nurse cells. The trophic chamber is connected to the egg chambers by nutritive cords. Egg chambers of telotrophic ovarioles contain only the oocyte surrounded by the follicle cells.

Endocrine control of female reproduction is governed by different types of hormones: neuropeptides (see **Chapter 3.10**), juvenile hormones (JHs; see **Chapter 3.7**), and ecdysteroids (see **Chapters 3.3** and **3.5**). In keeping with common practice among researchers in the field, ecdysteroid is used as the generic term for steroidal insect molting hormones, reserving the term ecdysone for the specific chemical compound 2β, 3β, 14α, 22R, 25-pentahydroxy-5β-cholest-7-en-6-one, originally known as α-ecdysone. The abbreviation 20E will be used to refer to 20-hydroxyecdysone (2β, 3β, 14α, 20R, 22R, 25-pentahydroxy-5β-cholest-7-en-6-one), the ecdysone metabolite believed to serve as the active hormone in most well-characterized responses. Individually, or in concert, the regulation of particular events during female reproduction by these hormones has evolved along with their effects on molting and metamorphosis. Control of female reproduction in Apterygota remains the most enigmatic. Studies of the firebrat, *Thermobia domestica* (Zygentoma), have shed some light on the hormonal regulation of vitellogenesis and ovarian development in primitive apterous insects (Bitsch and Bitsch, 1984; Bitsch *et al.*, 1986). In this insect, molting occurs continually into the adult stage, and oogenesis is coordinated with the ecdysteroid regulated adult molting cycle (Bitsch *et al.*, 1986). Treatment with the anti-allatal drug precocene blocks ovarian maturation, which indicates its dependence upon juvenile hormone secreted by the corpora allata (CA) (Bitsch and Bitsch, 1984; Bitsch *et al.*, 1986). Further studies are required in order to understand the precise roles of JH and ecdysteroids in regulating vitellogenesis and oogenesis in apterous insects.

It is well established that major events of reproduction in all insect orders with incomplete metamorphosis (Hemimetabola) are governed by JH. In the orders with complete metamorphosis (Holometabola), control strategies have evolved differently. In beetles (Coleoptera), JH remains the major regulatory hormone of reproductive events. In Hymenoptera, the role of JH is elaborated in eusocial species having a single or a few reproductive females in a colony (see **Chapter 3.13**). In Lepidoptera, female reproduction is regulated either by JH or ecdysteroids. In many such species, egg maturation occurs during the pharate adult stage and requires coordination with hormonal signals controlling metamorphosis. In dipteran insects, mosquitos, and flies, ecdysteroids have the leading role as hormonal regulators, but JH has an important role as a regulator in dipteran females in preparing reproductive tissues for ecdysteroid mediated events, such as vitellogenesis. For all insects, neuropeptides play a key role regulating the production of JH and ecdysteroids. A summary of the primary hormones involved in reproduction according to the phylogeny of insect orders is presented in **Figure 1**; for some orders, this is not known.

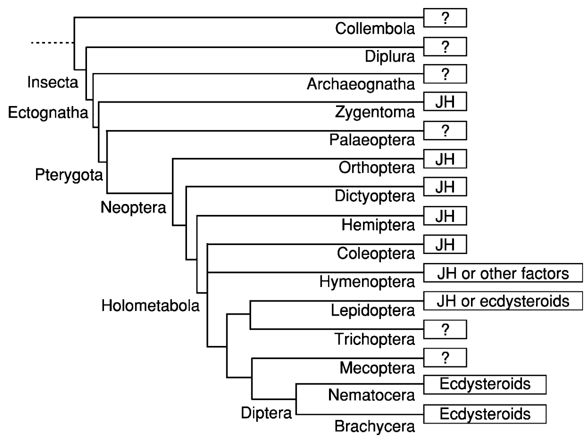

Figure 1 Utilization of juvenile hormone or ecdysteroids as major regulators of vitellogenesis and reproduction among insect orders. Some hemipterans show incomplete dependence on JH. In hymenopterans, JH plays a vitellogenic role in nonsocial and primitive social groups, but not in advanced groups (see **Chapter 3.13**). In lepidopterans, those species that begin vitellogenesis after adult emergence are JH dependent, and those in which vitellogenesis proceeds between pupal and adult stages are partially dependent on JH, whereas species in which vitellogenesis proceeds within or before the pupal stage are independent of JH. Dipterans, in general, are ecdysteroid dependent, although JH may play an accessory role in vitellogenesis (Modified from Belles, X., **2004**. Vitellogenesis directed by juvenile hormone. In: Raikhel, A.S., Sappington, T.W. (Eds.), Reproductive Biology of Invertebrates, Vol. 12, Part B: Progress in Vitellogenesis. Science Publishers, Enfield, USA/Plymouth, UK, pp. 157–198).

3.9.2.1.1. Juvenile hormone directed female reproduction In the adult females of Hemimetabola (Dictyoptera to Hemiptera) and Coleoptera, JH is the main regulator and pleiotropically controls most aspects of female reproduction (**Figure 2**). The major role of JH in reproduction is to regulate vitellogenin (Vg) gene expression in the fat body, generally, and in ovarian follicular epithelium (Wyatt and Davey, 1996; Engelmann, 1983, 2003; Belles, 2004). Some gryllid and hemipteran species show an incomplete dependence upon JH (Wyatt and Davey, 1996; Strambi *et al.*, 1997).

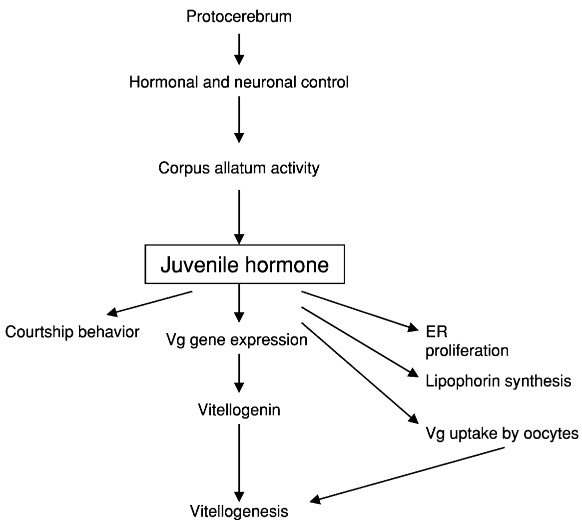

Figure 2 The pleiotropic role of juvenile hormone in insect reproduction. ER, endoplasmic reticulum; Vg, vitellogenin. (Reproduced with permission from Engelmann, F., **2003**. Juvenile hormone action in insect reproduction. In: Henry, H.L., Norman, A.W. (Eds.), Encyclopedia of Hormones, Vol. 2. Academic Press, San Diego, pp. 536–539.)

Cockroaches (Dictyoptera) are the classical model for studies of JH dependent vitellogenesis. In the oviparous *Periplaneta americana* (Blattidae), Weaver and Edwards (1990) have shown that allatectomy or treatment with inhibitors of JH synthesis blocks Vg production, oocyte growth, and ootheca formation, whereas JH treatment restores these processes. The regulation of vitellogenesis by JH has been most thoroughly studied in *Blattella germanica* (Blattellidae). In this typical JH dependent species, in which the females carry the ootheca externally until the first inside larvae emerge, JH production (Belles *et al.*, 1987), Vg titers (Martín *et al.*, 1995), and Vg mRNA levels (Comas *et al.*, 1999) show cyclical and approximately parallel patterns during the reproductive cycle (**Figure 3**). The pseudoviviparous cockroach, *Leucophaea maderae*, has been one of the favorite models for biochemical studies of JH regulation of reproduction. Effective doses to induce vitellogenesis in females *in vivo* range from 1 μg of JH I to 25 μg of JH III *in vivo*. Methoprene, a potent JH analog (JHA), induces vitellogenesis in adult males, as well (Don-Wheeler and Engelmann, 1997). In another pseudoviviparous cockroach, *Blaberus discoidalis*, allatectomy prevents ovarian maturation that can be restored by JH III treatment (Keeley and McKercher, 1985). In decapitated adult females, methoprene or JH III induces Vg protein synthesis (Keeley *et al.*, 1988) and a 6.5 kb mRNA, presumably corresponding to the Vg transcript (Bradfield *et al.*, 1990). The neuropeptide, hypertrehalosemic hormone, enhances the vitellogenic

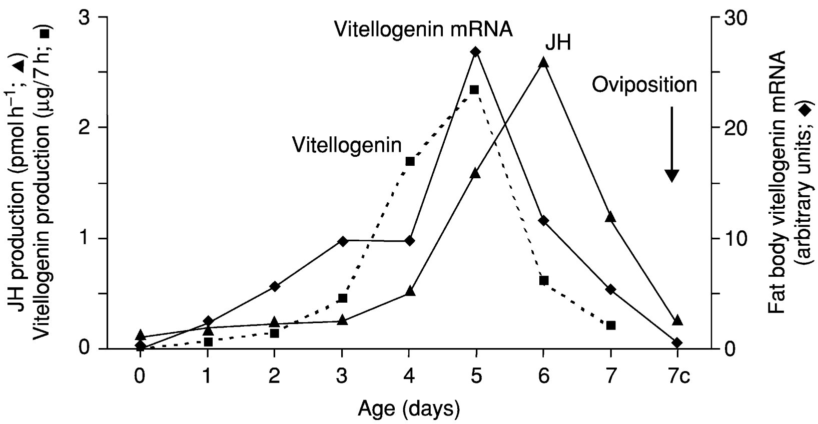

Figure 3 Production rates of juvenile hormone (JH) from the corpora allata, vitellogenin (Vg) from the periovarial fat body, and fat body Vg mRNA during the first reproductive cycle in the cockroach *Blattella germanica*. (Based on data from Belles, X., Casas, J., Messenguer, A., Piulachs, M.D., **1987**. *In vitro* biosynthesis of JH III by the corpora allata of *Blattella germanica* (L.) adult females. *Insect Biochem. 17*, 1007–1010; Martin, D., Piulachs, M.D., Belles, X., **1995**. Patterns of hemolymph vitellogenin and ovarian vitellin in the German cockroach, and the role of juvenile hormone. *Physiol. Entomol. 20*, 59–65; and Martin, D., Comas, D., Piulachs, M.D., Belles, X., **1998**. Isolation and sequence of a partial vitellogenin cDNA from the cockroach *Blattella germanica* (L.) (Dictyoptera, Blattellidae), and characterization of the vitellogenin gene expression. *Arch. Insect Biochem. Physiol. 38*, 137–146.)

effects of JH (Lee and Keeley, 1994a). In *Nauphoeta cinerea*, in which hemolymph Vg levels show a cyclic pattern during the gonadotropic cycle, JH I, II, and III can induce Vg production (Buschor and Lanzrein, 1983).

In Dermaptera, the CA are required for reproduction in female earwigs, *Anisolabis maritima*, as first shown by Ozeki (1951; see Rankin *et al.*, 1997), and JH is the main gonadotropic hormone in female *Euborellia annulipes*, which have vitellogenic cycles (Rankin *et al.*, 1997). Rouland *et al.* (1981) reported that allatectomized females *Labidura riparia* do not produce vitellogenic proteins, and 0.1 µg of farnesol, a precursor of JH, restores vitellogenesis.

In Orthoptera, the regulation of vitellogenesis by JH has been demonstrated in a number of locusts and grasshoppers (Acrididae) through classical experiments involving allatectomy and JH treatment (Wyatt, 1991; Wyatt and Davey, 1996). The most thoroughly studied orthopteran species has been *Locusta migratoria*, in which Vg synthesis is cyclic (Chinzei and Wyatt, 1985). Induction of Vg synthesis in female *L. migratoria* by JH homologs is only achieved with repeated doses or with high doses coinjected with a JH esterase inhibitor (Wyatt *et al.*, 1987), whereas synthetic JHAs at doses between 2 and 30 µg have a much more potent vitellogenic action (Edwards *et al.*, 1993; Zhang *et al.*, 1993). Neuropeptides may also be involved, since a brain factor enhances vitellogenesis induced by JH in fat body incubated *in vitro* (Glinka *et al.*, 1995). JH titer, and Vg protein and mRNA levels have been described during the reproductive cycle of the locust *Schistocerca gregaria* (Mahamat *et al.*, 1997) and the grasshopper *Romalea microptera* (= *Romalea guttata*) (Borst *et al.*, 2000).

In contrast to other orthopteroids, the phasmid *Carausius morosus* is independent of JH for vitellogenesis (Bradley *et al.*, 1995). Allatectomy does not prevent production of viable eggs in this insect, as first reported by Pflugfelder in 1930, and later confirmed with antibodies against *C. morosus* Vg that detected its production in allatectomized and intact females (Bradley *et al.*, 1995). However, it is not clear whether the independence from JH for vitellogenesis applies to all Phasmida.

In crickets (Gryllidae), both JH and ecdysteroids are involved in the control of vitellogenesis (review: Strambi *et al.*, 1997). In *Acheta domesticus*, the CA are necessary for oocyte growth, and JH restores vitellogenesis in allatectomized or decapitated females (Renucci *et al.*, 1987; Loher *et al.*, 1992). Conversely, female *Teleogryllus commodus* emerging from allatectomized larvae can still produce eggs (Loher and Giannakakis, 1990). Although allatectomy of *Gryllus bimaculatus* reduced the rate of egg production, oocytes in allatectomized females contained a similar amount of yolk protein as oocytes in controls; JH or JHA restored egg production to a variable extent (Hoffmann and Sorge, 1996). Notably, low doses of ecdysteroids stimulated oocyte growth in females of this species (Chudakova *et al.*, 1982; Behrens and Hoffmann, 1983). These results suggest that in crickets in which allatectomy does not completely suppress oocyte growth, ecdysteroids may play a vitellogenic role (Hoffmann and Sorge, 1996).

For Hemiptera, the CA were shown to be necessary for vitellogenesis in *Rhodnius prolixus* by V.B. Wigglesworth in the 1930s, and this observation has since been confirmed for several other hemipteran species (Wyatt and Davey, 1996; Davey, 1997; Belles, 2004). Later studies demonstrated that allatectomy of *R. prolixus* does not totally abolish Vg synthesis, but JH treatment does restore normal production (Wang and Davey, 1993). Female *Oncopeltus fasciatus* chemically allatectomized with precocenes produced the Vg precursor, but its conversion to mature Vg, which is incorporated into the oocytes, did not take place, as shown with electrophoresis of native proteins and immunodiffusion (Kelly and Hunt, 1982). A later study of this species found that the synthesis of two female specific Vg components, 200 and 170 kDa, was inhibited in precocene treated specimens and restored by administration of JH (Martinez and Garcerá, 1987). This discrepancy may be due to differences in the precocene treatment. Only one study has demonstrated a role for JH in a homopteran species. In the black bean aphid, *Aphis fabae*, ovarian development begins prenatally in this parthenogenic species, in such a manner that oocytes differentiate in the embryonic germaria, and at emergence each ovariole of a first instar aphid already contains one or two developing embryos. Precocene treatment of aphid nymphs inhibited oocyte development in embryos inside the parental ovaries, whereas JH reversed this inhibition (Hardie, 1987).

For Coleoptera, JH is the main gonadotropic hormone, but surprisingly little is known about the reproductive endocrinology of this holometabolous order with the greatest number of insect species. A long day regimen for the Colorado potato beetle, *Leptinotarsa decemlineata*, leads to reproductive activity and a short day induces diapause. JH or JHA (pyriproxyfen) treatment of short-day females induces Vg synthesis, and the JHA also induces Vg production in last instar larvae (de Kort *et al.*, 1997). Similarly, females of *Coccinella septempunctata*

reared on suboptimal artificial diets fail to reproduce, but Vg synthesis can be induced by treatment with JHA (Zhai *et al.*, 1984, 1987; Guan, 1989). In the spruce weevil, *Pissodes strobi*, treatment of previtellogenic females with JH III induces the precocious appearance of Vg transcripts, as determined by the identification of Vg mRNA (Leal *et al.*, 1997). This study also showed that Vg mRNA accumulates slower in beetles feeding on Sitka spruce trees (*Picea sitchensis*), which are resistant to *P. strobi* attack, thus suggesting that this plant contains anti-juvenoid compounds.

3.9.2.1.2. From nonsocial sawflies to eusocial ants and bees Within the Hymenoptera, JH appears to play a role in female reproduction among nonsocial and eusocial species and through this action may affect caste determination in the eusocial groups (see **Chapter 3.13**). In the primitive suborder Symphyta, only *Athalia* sawflies have received attention. JH applied to male *Athalia rosae* induced an increase in Vg production, and ovaries implanted into these males incorporated the Vg (Hatakeyama and Oishi, 1990). Later, it was shown that ovaries of *Athalia rosae* implanted into males of the closely related species, *Athalia infumata*, incorporated the heterospecific Vg that was induced in the host by JH III treatment (Hatakeyama *et al.*, 1995). Although these studies did not examine vitellogenesis in females, the results suggest a role for JH in females.

The regulation of reproduction by JH varies among the suborder Apocrita, which encompasses a range of species from solitary types to highly social groups like ants and honeybees (for reviews of JH action in social Hymenoptera see Robinson and Vargo, 1997; Hartfelder, 2000; **Chapter 3.13**). In the primitive eusocial paper wasps (Polistidae), *Polistes dominulus* (= *Polistes gallicus*) and *P. metricus*, JH acts as a gonadotropin. Queens or dominant females of *Polistes* show high JH titers associated with growing ovaries, whereas subordinate females have low JH titers. In general, allatectomy of dominant females leads to a reduction in the dominance status. The bumble bee, *Bombus terrestris* (Apidae), shows a relatively primitive social structure, and JH titers are high in egg laying queens. A regulatory role for JH is substantiated by the positive correlation between ovary development and rate of JH production in queenless workers (Block *et al.*, 2000). The role of JH remains unresolved among the studies of ants and bees with a complex social structure. JH treatment of isolated virgin queens of the fire ant, *Solenopsis invicta* (Myrmicinae) leads to wing shedding and oviposition, which is prevented by allatectomy. Subsequent JH treatment of allatectomized queens induces these phenomena (see Robinson and Vargo, 1997). Conversely, JH titers are low in reproductive female ants in the genus *Diacamma* (Ponerine; Sommer *et al.*, 1993). In the highly eusocial honeybee, *Apis mellifera* (Apidae), Vg synthesis in laying queens was only slightly reduced by allatectomy, and JH treatment increased ovary development only weakly (see Robinson and Vargo, 1997). Exogenous JH administered to queen and workers of *A. mellifera* advances the timing of vitellogenin appearance (Barchuk *et al.*, 2002); together, these results indicate that JH does not play a primary role in honeybee reproduction.

3.9.2.1.3. Butterflies and moths: endocrine compatibility of metamorphosis and vitellogenesis In Lepidoptera, some species begin vitellogenesis after adult emergence, and studies of Papilionoidea (e.g., *Pieris brassicae*, *Nymphalis antiopa*, *Polygonia caureum*, *Vanessa cardui*, and *Danaus plexippus*) and Noctuoidea (e.g., *Heliothis virescens*, *Helicoverpa zea*, and *Pseudaletia unipuncta*) show that JH stimulates vitellogenesis (see Cusson *et al.*, 1994a; Ramaswamy *et al.*, 1997). In *P. unipuncta*, the release rate of JH from CA *in vitro* is positively correlated with Vg synthesis (Cusson *et al.*, 1994b). In this species and *H. virescens*, vitellogenesis is abolished in decapitated females, and JH treatment restores it (Cusson *et al.*, 1994a; Ramaswamy *et al.*, 1997).

For other groups of Lepidoptera, egg development proceeds between the pupal and pharate adult stages. Studies of species in the Tortricoidea have shown that decapitation of female *Choristoneura fumiferana* and *C. rosaceana* reduces egg production, but Vg remains in the hemolymph (Delisle and Cusson, 1999). Treatment of the decapitated females with methoprene restores egg production. Similarly, treatment of female codling moths (*Cydia pomonella*) with fenoxycarb, a JHA, did not affect protein yolk content, but it did stimulate chorionation (Webb *et al.*, 1999). In this species, ecdysteroids may have a priming effect on vitellogenesis, since treatment with ecdysteroid agonists (tebufenozide and methoxyfenozide) increased levels of circulating Vg but did not affect its incorporation into the oocytes (Sun *et al.*, 2003). These results suggest that vitellogenesis is not completely dependent on JH and that it plays a primary role in Vg uptake by the oocyte and in chorionation in this family.

In the Sphingid (Bombycoidea) *Manduca sexta*, vitellogenesis starts 3–4 days before adult emergence and proceeds in the absence of the pupal CA; thereafter, JH is necessary to complete oocyte growth and chorionation (Satyanarayana *et al.*,

1994). Vg was present in prepupae of both sexes at low levels, had disappeared by pupal ecdysis, and reappeared in the late pharate adult females. Methoprene treatment induced Vg synthesis and Vg mRNA in prepupae and freshly molted pupae, and simultaneous administration of ecdysteroids abolished the vitellogenic action of JH (Satyanarayana *et al.*, 1994). The pyraloid moths studied to date have a similar reproductive physiology. In *Plodia interpunctella*, the declining ecdysteroid titer triggers vitellogenesis in early pupae, and ecdysteroid treatment inhibits vitellogenin uptake by the oocytes (Shirk *et al.*, 1992). Similarly, vitellogenesis in *Diatrea grandiosella* proceeds in the absence of ecdysteroids, whereas choriogenesis is completed with JH in the pharate adult (Shu *et al.*, 1997).

In non-Sphingid bombycoids, such as *Bombyx mori* (Bombycidae), *Hyalophora cecropia* (Saturniidae), and *Malacosoma pluviale* (Lasiocampidae), and in the lymantrid (Noctuoidea) *Lymantria dispar*, vitellogenesis proceeds before adult emergence in the absence of JH. In these groups, vitellogenesis seems totally independent of JH, as shown by allatectomy and JH treatment, which did not influence oocyte growth (see Wyatt and Davey, 1996 for references). Other studies of *L. dispar*, in which vitellogenesis starts as early as day 3 of the last larval instar, found that treatment with JHAs on day 2 of this instar selectively prevents the production of Vg (Fescemyer *et al.*, 1992) and Vg mRNA (Hiremath and Jones, 1992).

3.9.2.1.4. Mosquitos and flies: the shift to ecdysteroid mediated vitellogenesis For the Diptera, edysteroids have the primary role of regulating reproduction, as demonstrated in detail almost exclusively in mosquitos and flies. JH plays an important priming role in these females by preparing reproductive tissues for ecdysteroid mediated processes. Regulation of Vg production by ecdysteroids was first demonstrated in the yellow fever mosquito, *Aedes aegypti*. Vg synthesis in the mosquito fat body is stimulated by a blood meal and inhibited by removal of ovaries prior to blood feeding (Hagedorn and Fallon, 1973). The ovaries secrete the factor required for Vg production by the fat body, and this was found to be ecdysone (E), which is converted into the active form of the hormone 20-hydroxyecdysone (20E) (Hagedorn *et al.*, 1975). Remarkably, mosquitos and flies are the only insects known to use ecdysteroids as the key regulator of reproduction. How or why this shift away from JH- to ecdysteroid-mediated reproduction occurred in Diptera remains an enigma.

The endocrinology of vitellogenesis in mosquitos (suborder Nematocera) has been reviewed in detail for *A. aegypti* (Hagedorn, 1985; Raikhel, 1992a; Dhadialla and Raikhel, 1994; Sappington and Raikhel, 1998a; Raikhel *et al.*, 2003; Wang *et al.*, 2004) and investigated in *Culex pipiens*, *Aedes atropalpus*, and *Anopheles stephensi* (Hagedorn, 1985; Klowden, 1997). In *A. aegypti*, vitellogenesis is separated into four phases: previtellogenic (PV) preparation, arrest, yolk protein (YP) synthesis (vitellogenesis), and termination of vitellogenesis (Raikhel, 1992b; Dhadialla and Raikhel, 1994). A newly emerged female needs about 3 days to become competent for the physiological demands of intense vitellogenesis. During this phase, the fat body and ovary acquire responsiveness to 20E and become competent for blood meal-activated vitellogenesis and oogenesis, respectively (Flanagan *et al.*, 1977; Li *et al.*, 2000; Zhu *et al.*, 2003a). After 3 days of PV preparation, the fat body and ovary enter a state of arrest that persists until a blood meal is taken. During the YP synthesis stage, proteins are produced by the fat body and accumulated by developing oocytes (Raikhel, 1992a; Raikhel *et al.*, 2002). This massive synthesis peaks at around 24 h post-blood meal (PBM), then drops sharply, and terminates by 36–42 h PBM. The fat body undergoes remodeling, and the first batch of eggs completes chorion formation and is oviposited.

Titers of JH III and ecdysteroids in female *A. aegypti* are presented in **Figure 4**. During PV preparation, JH III titer increases and stabilizes during the arrest phase, and the CA remains active (Shapiro *et al.*, 1986). JH is required for the fat body to attain competence for YP synthesis in response to 20E. Following blood feeding, the JH III titer drops as a result of a rapid decrease in CA activity and elevation of JH esterase titer in the hemolymph (Shapiro *et al.*, 1986). Blood feeding triggers the release of the ovarian ecdysteroidogenic hormone (OEH) from the medial neurosecretory cells of the brain for up to 12 h postfeeding (**Figure 5**; Lea, 1972; Brown *et al.*, 1998). In response to OEH, the ovary produces ecdysteroids, and the hemolymph titer of ecdysteroids in female mosquitos is correlated with the rate of YP synthesis in the fat body (Hagedorn *et al.*, 1975). The ecdysteroid titers are only slightly elevated at 4 h PBM, rise sharply at 6–8 h PBM to a maximum level at 18–20 h PBM, and then decline to previtellogenic levels by 30 h PBM (Hagedorn *et al.*, 1975).

Numerous studies have clearly established that ecdysteroid control of YP synthesis is a central event in the blood meal-activated regulatory cascade

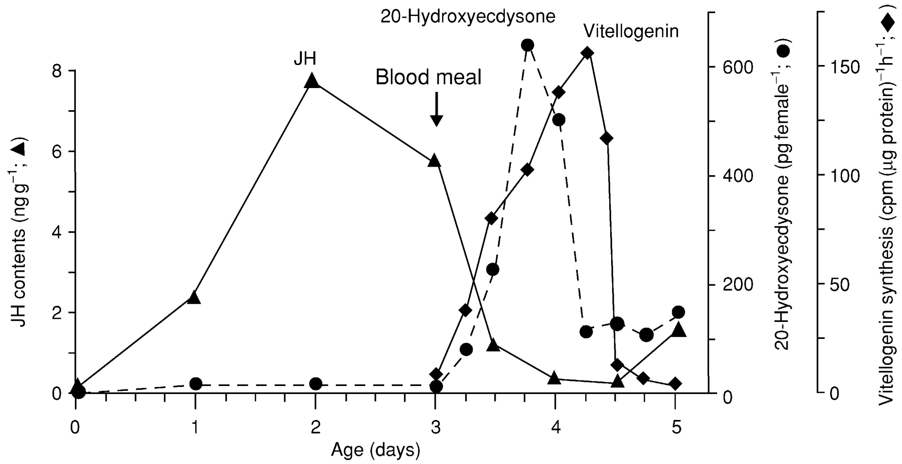

Figure 4 Juvenile hormone (JH) and 20-hydroxyecdysone titers and the level of Vg during the first reproductive cycle in the mosquito *Aedes aegypti*. (Based on data from Hagedorn, H., **1985**. The role of ecdysteroids in reproduction. Kerkut, G.A., Gilbert, L.I. (Eds.), Comprehensive Insect Physiology, Biochemistry and Pharmacology, Vol. 8. Pergamon, Oxford, pp. 205–261; and Dhadialla, T., Raikhel, A.S., **1994**. Endocrinology of mosquito vitellogenesis. In: Davey, K.G., Peter, R.E., Tobe, S.S. (Eds.), Perspectives in Comparative Endocrinology. National Research Council of Canada, Ottawa, pp. 275–281.)

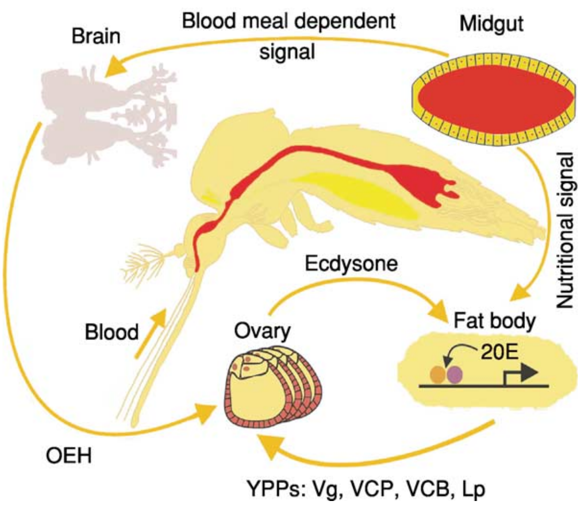

Figure 5 Schematic representation of the nutritional and hormonal activation of vitellogenesis in the mosquito *Aedes aegypti*. A blood meal results in a direct signal to the fat body, which is required to initiate yolk protein precursor (*YPP*) gene expression. The brain also receives a signal from the midgut, which activates medial neurosecretory cells to release a peptide hormone, ovarian ecdysteroidogenic hormone (OEH). OEH activates follicular cells of the primary follicles to produce ecdysone. Ecdysone is converted in the fat body to the active steroid hormone, 20-hydroxyecdysone (20E), which activates *YPP* gene expression via an ecdysone hierarchy. Yolk protein precursors, vitellogenin (Vg), vitellogenic carboxypeptidase (VCP), vitellogenic cathepsin B (VCB), and lipophorin (Lp) are secreted by the fat body into the hemolymph and selectively accumulated by developing oocytes.

leading to successful egg maturation (reviews: Hagedorn, 1985; Raikhel, 1992b; Dhadialla and Raikhel, 1994; Wang *et al*., 2004). Consistent with the proposed role of 20E in activating mosquito YP synthesis, experiments using fat body *in vitro* have shown that physiological doses of 20E (10^{-6} M) activate yolk protein precursor (*YPP*) genes, which are described below (Deitsch *et al*., 1995; Cho *et al*., 1999).

Molecular studies have demonstrated that although the ecdysteroid triggered regulatory hierarchies, such as those implicated in the initiation of metamorphosis, are reiteratively utilized in the control of mosquito vitellogenesis, the unique interplay of hierarchical factors is determined by the mosquito's biology (Raikhel *et al*., 2002, 2003; Wang *et al*., 2004). Of particular importance are the cyclicity of vitellogenic response and its dependence upon blood feeding. The demands for a very high level of expression of *YPP* genes, especially *Vg*, put additional restraints on the hormonal regulation of these genes.

The endocrine control of vitellogenesis in higher flies (suborder Cyclorrhapha) has been studied extensively in several species (reviews: Bownes, 1986, 1994, 2004; Raikhel *et al*., 2003) and is altered according to whether the species lays eggs in batches or continuously. In species laying eggs in batches, the maturation of a synchronous group of oocytes is controlled by changes in hormone levels, as described best for the housefly, *Musca domestica* (Adams and Filipi, 1983; Adams *et al*., 1985).

In this species, the fat body starts to synthesize YPs after the female fly feeds on a protein meal, and YP uptake also commences in the ovary. This phase is controlled by the circulating ecdysteroids, and the fat body later shuts down YP synthesis as egg development is completed. There is a strong correlation

between ecdysteroid titers in the hemolymph and the progress of vitellogenesis, as well as between ecdysteroid titers and the amount of YP produced in the fat body (Adams *et al*., 1985). Ovaries produce ecdysteroids *in vitro*, and ovariectomized flies have reduced ecdysteroid levels early in the cycle (Adams *et al*., 1985). In the autogenic strain of *M. domestica*, decapitation of females blocks Vg gene expression in fat body, but 20E restores accumulation of Vg mRNA. Moreover, males were induced to produce YPs in response to the hormone (Agui *et al*., 1991). JH acts at an early stage to prime the fat body for YP synthesis and ensures that the oocytes are arrested in a previtellogenic stage (Adams, 1974, 1981). Interestingly, Adams *et al*. (1989) also have shown that the response to 20E in male houseflies was enhanced by application of JH. Many aspects of the regulation of vitellogenesis in the housefly are quite similar to those described for *A. aegypti*.

In the blowfly, *Calliphora vicina*, YP-containing secretory granules become visible in the fat body when vitellogenesis is initiated by ingestion of a protein meal, but the granules are not detected in the fat body of ovariectomized females (Thomsen and Thomsen, 1974, 1978). Their appearance can be restored in ovariectomized females by injection of 20E (Thomsen *et al*., 1980). These observations have suggested the involvement of the ovary and ecdysteroids in the initiation of YP synthesis in the fat body of *C. vicina* and is reminiscent of the response of *A. aegypti* to a blood meal, which triggers the ovary to produce ecdysteroids and initiate a cycle of Vg production in the fat body.

In the blowflies, *Sarcophaga* and *Phormia*, non-protein-fed females respond to 20E by inducing YP synthesis in fat body (Huybrechts and De Loof, 1982). Unlike *C. vicina*, ovariectomized houseflies and blowflies still produce YPs indicating additional complexity of hormonal regulation in these insects (Engelmann and Wilkens, 1969; Jensen *et al*., 1981; Huybrechts and De Loof, 1982). Interestingly, male *Sarcophaga*, *Phormia*, and *Lucilia* also produce YPs in fat body in response to 20E injection (Huybrechts and De Loof, 1982). JH alone cannot induce YP synthesis in males in *Musca* or *Calliphora* (Adams, 1974; Huybrechts and De Loof, 1982; Adams *et al*., 1989).

In those species continuously laying eggs, each individual egg chamber differentiates, and its progress through vitellogenesis is modulated by hormonal signals connecting its development to environmental factors such as mating and food intake. This type of vitellogenesis is characteristic of *D. melanogaster*, and many related species. The regulation of vitellogenesis in *D. melanogaster* has been the subject of numerous studies using molecular, genetic, developmental, and physiological approaches (Bownes, 2004). In this species, adult sex determination (see **Chapter 1.5**) is the primary factor for correct expression of yolk protein genes. Once the genes are active in the female, the level of expression is modulated by ecdysteroids and JH in a complex way (Bownes *et al*., 1993; Bownes, 2004). JH seems crucial for vitellogenesis, especially in the ovary (Bownes *et al*., 1996; Soller *et al*., 1999), but it appears that JH does not directly affect the transcription of *yp* genes in the fat body. More recent data reported by Richard *et al*. (1998, 2001) points to a more prominent role for ecdysteroids in regulating vitellogenesis. It is interesting that in the Caribbean fruit fly, *Anastrepha suspensa*, in which the YPs are only produced in the ovary, there is no evidence of hormonal regulation by JH or 20E in females, and 20E injection is unable to stimulate YP synthesis in males (Handler, 1997).

3.9.2.2. Yolk Protein Precursors

3.9.2.2.1. Sites of yolk protein production In most insects, the fat body is the exclusive site for production of yolk protein precursors (YPPs) and, in others, the ovary is a complementary vitellogenic organ. **Table 1** provides a list of species in which fat body and ovarian YPP production have been reported, and in cyclorrhaphan Diptera, YPP synthesis occurs in both the fat body and the ovary. In some dipteran species, such as the stable fly *Stomoxys calcitrans*, *Anastrepha suspensa* and perhaps the tsetse fly *Glossina austeni*, the ovary is the exclusive site of YPP synthesis (review: Wyatt and Davey, 1996). Insect YPs are the subject of several recent reviews (Bownes and Pathirana, 2002; Sappington *et al*., 2002; Telfer, 2002; Tufail *et al*., 2004; Masuda *et al*., 2004; Yamahama *et al*., 2004).

3.9.2.2.2. The fat body In female insects, the main function of the fat body is to produce massive amounts of YPPs. Multiple lobes of this organ are distributed mainly in the abdomen and to a lesser extent in the thorax and head. In many insects, fat body consists of a single cell type, the trophocyte (= adipocyte), and in cockroaches and some other insects, mycetocytes and urate cells are also present (Kelly, 1985; Locke, 1998). The multilobed structure of this tissue enhances its interaction with hemolymph. Also, the fat body is responsible for intermediary metabolism; storage of carbohydrates,

Table 1 Vitellogenic organs in insects

Order–suborder	Species	Vitellogenic organ: Fat body	Ovary	Type of ovarioles
Zygentoma	*Thermobia domestica*[a]	X	X	Panoistic
Dictyoptera	*Blattella germanica*[b]	X		Panoistic
Dictyoptera	*Leucophaea maderae*[b]	X		Panoistic
Orthoptera–Caelifera	*Locusta migratoria*[b]	X		Panoistic
Orthoptera–Ensifera	*Acheta domesticus*[b]	X		Panoistic
Phasmida	*Bacillus rossius*[b]	X		Panoistic
Hemiptera	*Rhodnius prolixus*[c]	X	X	Telotrophic meroistic
Coleoptera	*Leptinotarsa decemlineata*[b]	X	X	Telotrophic meroistic
Coleoptera	*Coccinella septempunctata*[b]	X	X	Telotrophic meroistic
Hymenoptera	*Apis mellifera*[d]	X	X	Polytrophic meroistic
Lepidoptera	*Plodia interpunctella*[b]	X		Polytrophic meroistic
Lepidoptera	*Hyalophora cecropia*[b]	X		Polytrophic meroistic
Lepidoptera	*Manduca sexta*[b]	X		Polytrophic meroistic

lipids, and proteins; and synthesis of hemolymph proteins. These functions are hormonally controlled and successively change in accordance with the demands of different life stages.

Trophocytes are equipped with abundant cytoplasmic organelles that accomplish a great variety of synthetic and secretory functions. The basal lamina enveloping the fat body allows diffusion of large oligomeric proteins with molecular sizes of over 300 000 (even up to 500 000 Da) and keeps the apical plasma membrane of trophocytes structurally differentiated. This apical membrane is highly infolded and resembles a plasma membrane reticular system in which secretory granules are being released by exocytosis (Locke and Huie, 1983; Raikhel and Lea, 1983; Dean *et al.*, 1985; Raikhel and Snigirevskaya, 1998; Mazzini *et al.*, 1989; Giorgi *et al.*, 2004).

3.9.2.2.3. Fat body derived yolk protein precursors

3.9.2.2.3.1. Vitellogenins In most female insects, the major constituent of protein yolk is Vg, a large, conjugated protein that is taken into oocytes and stored as vitellin (Vn). The amino acid sequence, structure, and composition of Vg are sufficiently conserved between insects and other oviparous animals to indicate origin from a common ancestral protein (Chen *et al.*, 1994; Sappington and Raikhel, 1998a; Sappington *et al.*, 2002) and may share homology with other, more distantly related lipoproteins (Blumenthal and Zucker-Aprison, 1987; Spieth *et al.*, 1991; Sappington *et al.*, 2002). Insect Vgs are encoded by mRNAs of 6–7 kb that are translated as primary products of ~200 kDa. Vg primary products have been characterized at the molecular level for Hemimetabola and Holometabola species (Sappington *et al.*, 2002; Tufail *et al.*, 2004).

The primary pre-proVg is cleaved into subunits (apoproteins), ranging from 50 to 180 kDa, by subtilisin-like endoproteases and proprotein convertases (Barr, 1991; Rouille *et al.*, 1995). These enzymes recognize a consensus motif (R/K)XX(R/K) preceding the cleavage site, and the motif is found in all known insect Vgs (Chen *et al.*, 1994; Sappington and Raikhel, 1998a; Sappington *et al.*, 2002; Tufail *et al.*, 2004). Vg convertase (VC) has been characterized from the vitellogenic fat body of

A. aegypti (Chen and Raikhel, 1996) and is a homolog of human and *D. melanogaster* furins and a *D. melanogaster* convertase (Barr *et al*., 1991; Roebroek *et al*., 1991, 1992a, 1992b; Hayflick *et al*., 1992).

In hemimetabolous insects like *L. maderae*, *P. americana*, and *Riptortus clavatus*, the Vg primary product is cleaved into large and small polypeptides, including polypeptides of ~80–110 kDa (**Figure 6**) (Della-Cioppa and Engelmann, 1987; Hirai *et al*., 1998; Tufail *et al*., 2001; Tufail and Takeda, 2002). It has also been reported that Vgs from some hemimetabolous insects, such as *L. maderae* and *R. clavatus*, are processed further in the oocyte (Hirai *et al*., 1998; Tufail and Takeda, 2002).

In holometabolous insects, the Vg primary product is cleaved into a single large and small polypeptide (**Figure 6**) (Dhadialla and Raikhel, 1990; Chen *et al*., 1994, 1996). As with other apocritan Hymenoptera, Vg is not cleaved in the parasitic wasp, *Pimpla nipponica* (**Figure 6**; Nose *et al*., 1997). In the fall armyworm moth, *Spodoptera frugiperda*, only a single Vg apoprotein was detected in hemolymph and ovarian extracts, although other lepidopteran Vgs normally are processed into two subunits (Hiremath and Lehtoma, 1997; Sorge *et al*., 2000).

Following extensive co- and posttranslational modifications, Vg subunits form high molecular weight oligomeric phospholipoglycoproteins (400–600 kDa) that are secreted into the hemolymph of females (Osir *et al*., 1986a; Wojchowski *et al*., 1986; Dhadialla and Raikhel, 1990; Sappington and Raikhel, 1998a; Giorgi *et al*., 1998; Tufail *et al*., 2004). Mature vitellogenins generally exist as oligomers, but monomeric molecules of about 300 kDa may exist in the cockroach *N. cinerea* (Imboden *et al*., 1987).

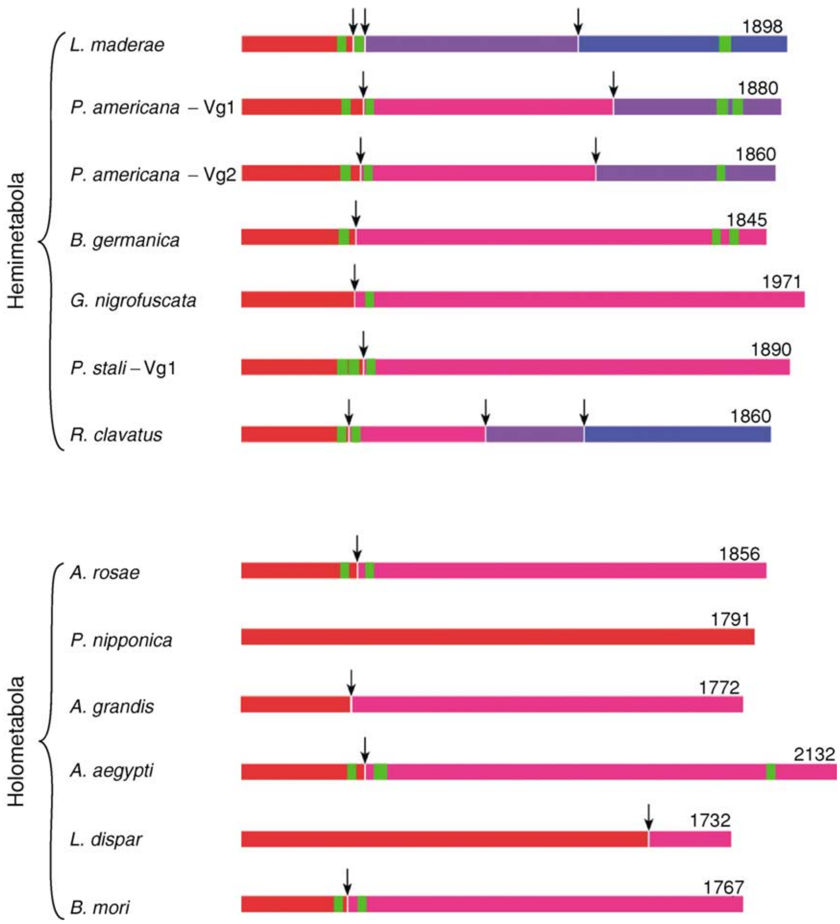

Figure 6 Schematic representation of the cleavage sites and polyserine domains in vitellogenins from 12 insect species. The arrows and white lines indicate the putative or determined cleavage sites following the consensus RXXR cleavage site sequence. The green segments show the polyserine stretches. Numbers indicate the amino acid residues deduced from the N-termini (excluding the signal peptides). Color code is used to indicate the number of vitellogenin subunits resulting from proteolytic cleavage. (Modified from Tufail, M., Raikhel, A.S., Takeda, M., **2004**. Biosynthesis and processing of insect vitellogenins. In: Raikhel, A.S., Sappington, T.W. (Eds.), Reproductive Biology of Invertebrates, Vol. 12, Part B: Progress in Vitellogenesis. Science Publishers, Enfield, USA/Plymouth, UK.)

One to several *Vg* genes have been identified in different insect species (reviews: Telfer, 2002; Tufail *et al.*, 2004). In the silkworm *B. mori*, *Vg* is encoded by a single gene (Tufail *et al.*, 2004), and there are five *Vg* genes in the mosquito *A. aegypti* (Romans *et al.*, 1995). Regulatory regions of *Vg* genes that govern hormone dependent expression have been characterized in great detail for *A. aegypti* (Kokoza *et al.*, 2001) and only partially for *L. migratoria* and *B. germanica* (Wyatt *et al.*, 1984; Locke *et al.*, 1987; Belles, 2004).

3.9.2.2.3.2. Yolk polypeptides of the cyclorrhaphous Diptera In higher Diptera, the number of YPs ranges from one to five, and they are different from the Vg of other insects (review: Bownes and Pathirana, 2002). There are three major YPs of 46, 45, and 44 kDa (Barnett *et al.*, 1980; Bownes *et al.*, 1993) in *D. melanogasti* and up to five YPs ranging from 40 to 51 kDa in *C. erythrocephala* (Fourney *et al.*, 1982), *Neobellieria* (= *Sarcophaga*) *bullata* (Huybrechts and De Loof, 1982), *M. domestica* (Adams and Filipi, 1983), *A. suspensa* (Handler, 1997), *Phormia regina* (Zou *et al.*, 1988), *Ceratitis capitata* (Rina and Savakis, 1991), and eight other species of *Drosophila* (Bownes, 1980). The primary translation products of cyclorrhaphan YPs are close to the size of each mature polypeptide. Their post-translational modification includes glycosylation and phosphorylation and tyrosine sulfation (Brennan *et al.*, 1980; Minoo and Postlethwait, 1985; Baeuerle and Huttner, 1985).

Yolk protein genes have been characterized for *D. melanogaster* (Hung and Wensink, 1983; Garabedian *et al.*, 1987; Yan *et al.*, 1987), *C. capitata* (Rina and Savakis, 1991), and *C. erythrocephala* (Martinez and Bownes, 1994). Deduced amino acid sequences for the three YPs of *D. melanogaster* show that they are related to each other and to other cyclorrhaphan YPs. These YPs are not lipoproteins (see **Chapter 4.6**), likely constitute subunits of a larger native protein (Fourney *et al.*, 1982; Adams and Filipi, 1983; Zou *et al.*, 1988), and more closely resemble a family of vertebrate lipases and not the insect Vgs (Bownes *et al.*, 1988; Terpstra and Ab, 1988).

3.9.2.2.3.3. Additional yolk proteins secreted by the fat body A number of supplemental proteins are secreted by the fat body of vitellogenic females and selectively accumulated by developing oocytes. Typically, these YPs are minor yolk components but in some species can be as abundant as Vg (Telfer, 2002; Masuda *et al.*, 2004). Most are female-specific products, but some are found in the hemolymph of both sexes. They are likely to serve specialized functions necessary for embryonic development and, as yet, it is difficult to draw any unifying conclusions, since very few of these YPs have been characterized for insects.

3.9.2.2.3.3.1. Microvitellogenin Microvitellogenin (mVg) is a small yolk protein of 30 kDa (Pan, 1971; Kawooya *et al.*, 1986; Telfer and Pan, 1988; Pan *et al.*, 1994). In lepidopteran species, mVg is synthesized and secreted by the fat body (Cole *et al.*, 1987) and incorporated by ovarian follicles (Telfer and Kulakosky, 1984; Kulakosky and Telfer, 1989). *Manduca sexta* mVg is a monomeric protein with no detectable carbohydrate, lipid, or phosphate (Kawooya *et al.*, 1986). *Bombyx mori* produces multiple 30 kDa proteins that are the principal components of both male and female hemolymph during late larval and pupal stages (Izumi *et al.*, 1981) and constitute 35% of the egg total soluble protein (Zhu *et al.*, 1986). Deduced amino acid sequences from five *B. mori* mVg cDNA clones revealed their high similarity (Sakai *et al.*, 1988), and *M. sexta* mVg shares 70% sequence similarity with a *B. mori* mVg (Wang *et al.*, 1989). Furthermore, antigenic similarity between mVgs in *M. sexta* and *H. cecropia* (Kawooya *et al.*, 1986) supports the homology of lepidopteran mVgs.

3.9.2.2.3.3.2. Lipophorin as a yolk protein Lipids are a critical source of energy during insect embryogenesis (Beenakkers *et al.*, 1985) and can represent as much as 30–40% of the egg's dry weight (Troy *et al.*, 1975; Kawooya and Law, 1988; Briegel, 1990). Lipophorins (Lp) are lipid transport proteins in insects (see **Chapter 4.6**) and play a prominent role in the accumulation of lipids in insect oocytes (review: Antwerpen van *et al.*, 2004). Kinetic analyses have indicated that lipid transfer is affected by a saturable mechanism in both *M. sexta* (Kawooya and Law, 1988) and *H. cecropia* (Kulakosky and Telfer, 1990), thus indicating that lipid uptake occurs via receptor-mediated endocytosis. Specific ovarian receptors for Lp have been cloned from *L. migratoria* (Dantuma *et al.*, 1997), *A. aegypti* (Cheon *et al.*, 2001), and *B. germanica* (Ciudad, Piulachs, and Belles, unpublished data). In saturniid and sphingid moths, Lp is the second most abundant YP (Chino *et al.*, 1977b; Telfer *et al.*, 1991; Telfer and Pan, 1988), and it has been found in the yolk of the fall webworm *H. cunea* (Arctiidae) (Yun *et al.*, 1994). In mosquito eggs, Lp makes up only 3% of total egg proteins (Sun *et al.*, 2001). In *B. germanica*, Lp facilitates hydrocarbon uptake by maturing oocytes (Fan *et al.*, 2002).

3.9.2.2.3.3.3. Pro-proteases Yolk proteins are essential reserves of amino acid and other nutrients for the developing insect embryos, and sequential cleavage of YPs into smaller molecules occurs throughout embryogenesis (Zhu *et al.*, 1986; Yamashita and Indrasith, 1988; Masetti and Giorgi, 1989; Yamamoto and Takahashi, 1993; Izumi *et al.*, 1994; Takahashi *et al.*, 1996; Cho *et al.*, 1999; Yamahama *et al.*, 2004). This proteolytic degradation of YPs is probably regulated through a battery of proteases (see **Chapter 4.7**).

At present, two female-specific proenzymes are known to be deposited in the protein yolk of *A. aegypti*. One is a serine carboxypeptidase, vitellogenic carboxypeptidase (VCP), and it is a glycosylated 53 kDa protein secreted by the female fat body in synchrony with vitellogenin (Hays and Raikhel, 1990). An antigenically similar protein of the same size occurs in the yolk, and the enzyme is activated during embryogenesis by cleavage to a 48 kDa polypeptide (Cho *et al.*, 1991). A 44 kDa fat body protein, vitellogenic cathepsin B (VCB), with sequence similarity to vertebrate cathepsin B is also incorporated into the yolk of *A. aegypti* (Cho *et al.*, 1999). It is converted to 42 kDa after internalization in developing oocytes, and then to 33 kDa in developing embryos, coinciding with the onset of YP degradation. The 33 kDa protein degrades mosquito YPs *in vitro*. Secretory pathways for VCP and VCB in the fat body and their endocytosis in the oocyte were shown by immunocytochemistry to be the same as those of vitellogenin (Snigirevskaya *et al.*, 1997a). Notably, they are deposited in the amorphous, peripheral layer of the yolk bodies surrounding the central core of the vitellin crystal (Snigirevskaya *et al.*, 1997b).

An acid cysteine proteinase (see **Chapter 4.7**) was first purified from *Bombyx* eggs (Kageyama and Takahashi, 1990) and named *Bombyx* cysteine proteinase (BCP). It has broad substrate specificity and hydrolyzes various protein substrates, including *B. mori* yolk proteins. Since BCP accumulates in hemolymph, it is secreted by the fat body as shown by Northern blots. Ovarian follicle cells also synthesize the enzyme, as established by Northern blot and its synthesis from ovarian RNA (Yamamoto *et al.*, 2000).

3.9.2.2.3.3.4. Other fat body products used as yolk proteins For several insects, there are reports of other proteins that are incorporated into yolk. In *L. migratoria* females, 21 kDa and 25 kDa proteins are produced by the fat body in synchrony with the synthesis of Vg (Zhang *et al.*, 1993; Zhang and Wyatt, 1996) and accumulate in oocytes along with Vg. These additional yolk proteins are significant constituents of the yolk in *L. migratoria* eggs. In the lepidopteran *M. sexta*, a blue biliprotein (insecticyanin) composed of four 21.4 kDa subunits is a component of larval hemolymph and is present in eggs (Chino *et al.*, 1969; Kang *et al.*, 1995). An arylphorin-like cyanoprotein that is a hemolymph storage hexamer is also deposited in eggs of the bean bug *R. clavatus* (Chinzei *et al.*, 1990; Miura *et al.*, 1994). The incorporation of these pigmented proteins may help to conceal eggs from predators (Chino *et al.*, 1969). The iron transport protein, transferrin (see **Chapter 4.10**) has been shown to be selectively deposited in yolk of the flesh fly *Sarcophaga peregrina* (Kurama *et al.*, 1995) and the bean bug *R. clavatus* (Hirai *et al.*, 2000). Hemolymph and oocytes of *Rhodnius prolixus* also contain a 15 kDa heme binding protein (Oliveira *et al.*, 1995). Eggs of the stick insect *C. morosus* contain a minor yolk protein that is secreted by the fat body and sulfated by the follicle cells (Giorgi *et al.*, 1995).

3.9.2.2.4. Yolk proteins synthesized by ovarian follicle cells Irrespective of insect ovary type, only the follicle cells in egg chambers engage in the production of proteins that are utilized as YPs. As demonstrated for several insects, follicle cells secrete a protein that has a similar antigenic reactivity and subunit composition as the Vg produced by fat body. In the firebrat *T. domestica*, there is the dual origin of YP from fat body and ovaries (Rousset and Bitsch, 1993) (**Table 1**). The synthesis of YPs by both tissues in adult females of this order, where molting and reproduction alternate, indicates that it could be an ancestral condition. YP production has also been observed in ovarian follicles of the heteropteran *R. prolixus* (Melo *et al.*, 2000) and two coleopterans, *C. septempunctata* (Zhai *et al.*, 1984) and *L. decemlineata* (Peferoen and De Loof, 1986). In the honeybee, *A. mellifera*, Vg expression has been reported in the fat body (Piulachs *et al.*, 2003), but a more recent study has revealed that it is also expressed in the ovaries (K.R. Guidugli, M.D. Piulachs, X. Belles, and Z.L.P. Simões, unpublished data). These findings in *R. prolixus* and *A. mellifera* suggest the importance of reassessing the vitellogenic role of the ovary in more species.

In higher flies (suborder Cyclorrhapha), the ovarian origin of YPs was first detected in *D. melanogaster* (Bownes and Hames, 1978), and in this and other species, these YPs have been investigated extensively (see Section 3.9.2.2.3.2). Follicle cells were identified as the site of synthesis in *D. melanogaster*

by their ability to secrete YPs when manually separated from follicles labeled with [^{35}S]methionine, and by *in situ* hybridization to contain YP mRNAs (Brennan *et al.*, 1982). Follicle cells are implicated in production of YPs in *C. erythrocephala* (Rubacha *et al.*, 1988) and in *S. bullata* (Geysen *et al.*, 1986). In the stable fly, *S. calcitrans* (Houseman and Morrison, 1986; Chen *et al.*, 1987), the Caribbean fruit fly *A. suspensa* (Handler and Shirk, 1988; Handler, 1997), and the tsetse fly, *glossina austeni* (Huebner *et al.*, 1975), female specific proteins do not occur in the hemolymph of reproductive adults, thus indicating that YPs are synthesized only in the ovaries.

In some cyclorrphan flies, YP genes are expressed differently in the fat body and follicular epithelium. In *C. erythrocephala*, ovaries produced 51 and 49 kDa YPs, while fat body secreted a 46 kDa YP and possibly a different 49 kDa YP (Fourney *et al.*, 1982). In *D. melanogaster*, the two tissues secrete the same three YPs, but the smallest one, YP3, is underrepresented in ovarian synthesis (Brennan *et al.*, 1982; Isaac and Bownes, 1982). Ovarian and fat body YPs are mixed in the eggs of these flies.

In several species of Lepidoptera, follicle cells secrete proteins that are incorporated into yolk and may account for up to 25% of the total soluble protein, as in mature eggs of *B. mori* (Zhu *et al.*, 1986). In the moth *H. cecropia*, a 55 kDa protein is present in the intercellular spaces and yolk bodies (Bast and Telfer, 1976). Follicles of *B. mori* produce an ovary specific protein of 225 kDa with three 72 kDa subunits (Ono *et al.*, 1975; Indrasith *et al.*, 1988; Sato and Yamashita, 1991a); one of which is converted to a 64 kDa polypeptide by egg maturation. Sequencing of a cDNA clone revealed its similarities to human gastric and rat lingual lipases, especially to a noncatalytic lipid binding domain (Inagaki and Yamashita, 1989; Sato and Yamashita, 1991b). Two follicle specific YPs have also been isolated from *M. sexta* (Tsuchida *et al.*, 1992). One is a 130 kDa protein consisting of two glycosylated and phosphorylated 65 kDa subunits, similar to those of the follicle cell derived yolk protein of *B. mori*. The second is a slightly larger 140 kDa protein that is glycosylated but not phosphorylated. In the pyralid moth *P. interpunctella*, two yolk polypeptides originate in the follicle cells, and the 235–264 kDa protein with subunits of 69 and 33 kDa is an ortholog of the egg specific protein in *B. mori* (Shirk *et al.*, 1984; Bean *et al.*, 1988; Shirk and Perera, 1998). Sequences for a cDNA clone encoding YP4 of *P. interpunctella* (Perera and Shirk, 1999) showed it to be an ortholog of a follicular product in *G. mellonella* (Rajaratnam, 1996).

3.9.2.3. Mechanisms of Juvenile Hormone Action in Vitellogenesis

3.9.2.3.1. Induction of vitellogenin gene expression Vitellogenic action of JH is one of the hallmarks of insect reproduction. Although JH is known to initiate vitellogenesis in many insects (see **Chapter 3.7**), its precise mechanism of action is poorly understood. Studies of the induction of *Vg* gene transcription by JH have focused on two species: the migratory locust, *L. migratoria*, and the German cockroach, *B. germanica* (Wyatt, 1991, 1997; Belles, 2004).

Two *Vg* genes have been partially characterized in *L. migratoria*, and studies at the molecular level have demonstrated the absence of detectable Vg mRNA in the fat body of JH deprived specimens (Dhadialla *et al.*, 1987). Transcription of both *Vg* genes is coordinately induced *in vivo* by JH or JHA (Dhadialla *et al.*, 1987; Glinka and Wyatt, 1996), but allatectomized locust females have a low sensitivity to JH, since doses up to 100 μg of JH III do not induce Vg production. JHAs, such as methoprene or pyriproxyfen, are more potent and stable (Wyatt *et al.*, 1996). When JHA is administered to females chemically allatectomized with the allatocide precocene within 1 day of adult emergence, there is a lag of 12–24 h before Vg mRNA can be detected (Edwards *et al.*, 1993). This lag period can be shortened by prior administration of a subeffective dose of JH or JHA that is insufficient by itself to induce *Vg* gene transcription. This dose likely primes the fat body cells for an accelerated response to a subsequent effective dose (**Figure 7**) (Edwards *et al.*, 1993; Wyatt *et al.*, 1996). The lag period between JHA treatment and vitellogenesis can be extended by inhibition of protein synthesis with cycloheximide (**Figure 7**) (Edwards *et al.*, 1993). These results suggest that the action of JH on *Vg* genes in locust females is indirect and requires the synthesis of protein factors involved in transcription. In this respect, the priming action of JH on fat body for a vitellogenic response is similar to that in mosquitos in which the molecular nature of this JH action has been recently elucidated (Zhu *et al.*, 2003a).

Studies on the regulation of vitellogenesis in *B. germanica* also were facilitated by the cloning of a Vg cDNA (Martin *et al.*, 1998; Comas *et al.*, 2000). Experiments *in vivo* with allatectomized females have shown that Vg mRNA can be detected as early as 2 h after treatment with 1 μg of JH III, whereas Vg protein can be detected 2 h later (**Figure 8**). In addition, dose–response studies show that doses of 0.1, 1, and 10 μg of JH III induced Vg

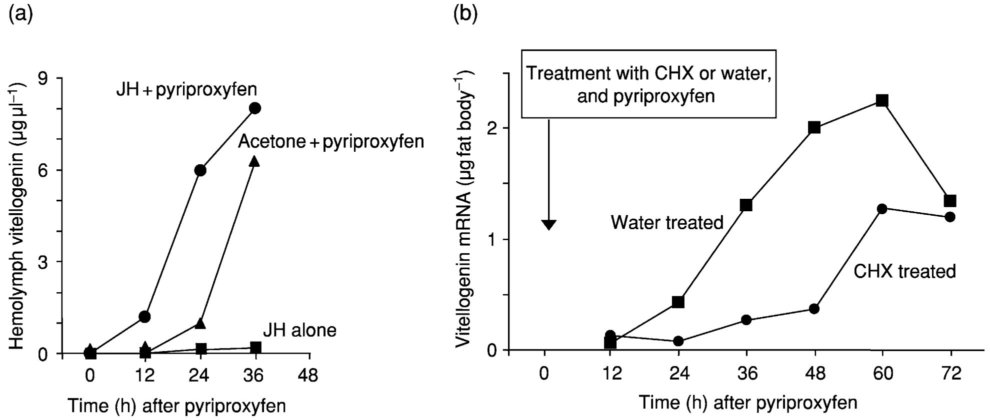

Figure 7 Induction of vitellogenin transcription in chemically allatectomized females of the migratory locust, *Locusta migratoria*. (a) Shortening of the response lag time by administration of a subeffective dose of JH. Specimens pretreated with low doses of JH III in acetone (four applications of 10 μg each, over 48 h) and then treated with 10 μg of pyriproxyfen, synthesize vitellogenin earlier (circles) than those receiving an equivalent treatment of acetone alone and pyriproxyfen (triangles). Equivalent pretreatment with JH III, but no pyriproxyfen, did not induce detectable vitellogenin synthesis (squares). (Data from Wyatt, G.R., Braun, R.P., Zhang, J., **1996**. Priming effect in gene activation by juvenile hormone in locust fat body. *Arch. Insect Biochem. Physiol. 32*, 633–640.) (b) Inhibitory effects of cycloheximide (CHX) upon vitellogenesis induced by pyriproxyfen. Insects were treated with cycloheximide (62 μg) in water or with water alone, and 1 h later treated with 10 μg pyriproxyfen. Cycloheximide delayed vitellogenin transcription by about 1 day, which is approximately equal to the duration of inhibition of protein synthesis. (Reproduced with permission from Edwards, G.C., Braun, R.P., Wyatt, G.R., **1993**. Induction of vitellogenin synthesis in *Locusta migratoria* by the juvenile hormone analog, Pyriproxyfen. *J. Insect Physiol. 39*, 609–614.)

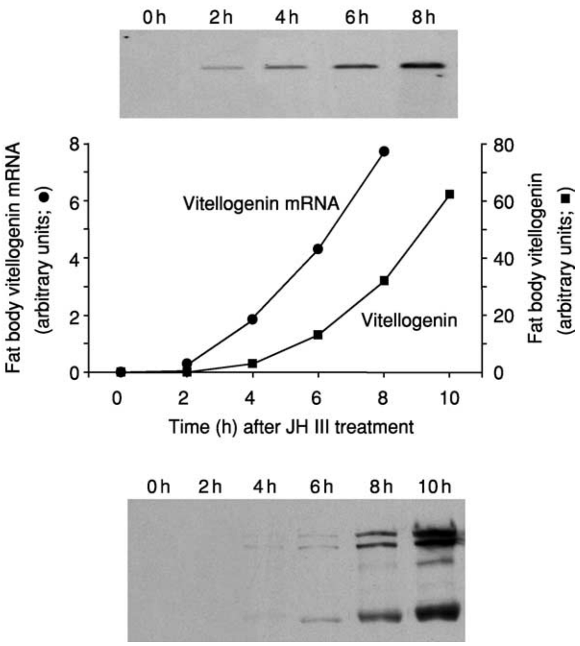

Figure 8 Production of vitellogenin mRNA and vitellogenin protein *in vivo* after JH treatment of allatectomized females of *Blattella germanica*. A dose of 1 μg of JH III was topically applied to 48 h old allatectomized females; the fat body was dissected 2, 4, 6, 8, or 10 h later, and analyzed for vitellogenin mRNA (Northern blot, above), or vitellogenin protein (Western blot, below). (Reprinted with permission from Comas, D., Piulachs, M.D., Belles, X., **1999**. Fast induction of vitellogenin gene expression by juvenile hormone III in the cockroach *Blattella germanica* (L.) (Dictyoptera, Blattellidae). *Insect Biochem. Mol. Biol. 29*, 821–827, with permission from Elsevier.)

synthesis, but not 0.01 μg (Comas *et al.*, 1999, 2001). Cycloheximide applied to fat body *in vitro* abolishes the vitellogenic effects of JH (Comas *et al.*, 2001), again suggesting that the effect of JH on the *Vg* gene involves the synthesis of protein factors involved in transcription.

3.9.2.3.2. Potential response elements in JH-dependent genes related to vitellogenesis Results from the above studies of JH action on vitellogenesis in the locust and cockroach led to the hypothesis that JH may affect proteins belonging to the nuclear hormone receptor superfamily (see **Chapters 3.5** and **3.6**), which in turn would mediate transcription of Vg genes (Wyatt *et al.*,1996; Belles, 2004; see **Chapter 3.5**). Signature response elements for the binding of the putative JH transcription factors could be found within the regulatory regions of these genes, in the same way as those for the ecdysteroid receptor (EcR) and related proteins.

Analysis of the *jhp21* gene of *L. migratoria* revealed the partially palindromic, 13-nucleotide motif AGGTTCGAG^{A}/$_{T}$CCT that is found in three copies from the transcription start point (Zhang and Wyatt, 1996). This motif is suggestive of a hormone response element, given that it is similar to the consensus ecdysteroid response element (see **Chapter 3.5**), as defined by Jiang *et al.* (2000). Furthermore, this nucleotide motif is very similar to the canonical sequence IR-1 (AGGTCAATGACCT), a

consensus-inverted repeat with a single nucleotide spacer that is recognized by the ecdysteroid receptor and that confers JH responsiveness upon genes in mammalian cells that contain farnesoid x receptor (FXR), a member of the nuclear receptor superfamily (Forman *et al*., 1995).

3.9.2.3.3. Molecular mechanisms in juvenile hormone action Hypothesized JH specific DNA motifs require functional characterization, either by demonstrated activity in gene regulation or by binding to a known JH receptor or a transcription factor involved in JH response. Significant progress in this regard has been made on the 13-nucleotide motif AGGTTCGAG$^{A}/_{T}$CCT from the upstream region of the *jhp21* gene in *L. migratoria*. A cell-free transcription system was developed that uses nuclear proteins extracted from locust fat body, and transcription is measured with reporter constructs containing a short DNA sequence, lacking G in the transcribed strand, fused to the promoter sequence of interest (Zhang *et al*., 1996). When transcription is carried out with the transcription terminator *O*-methyl-GTP and not GTP, only the DNA sequence lacking G is transcribed, and the transcript can be resolved by gel electrophoresis. With nuclear extracts from untreated adult female *L. migratoria*, constructs that include the promoter region of the vitellogenin or *jhp21* genes are transcribed, as is also the nonspecific promoter of the adenovirus major late antigen (*AdML*), which is used as a positive control. However, extracts from precocene treated females, while still transcribing *AdML*, fail to transcribe from the *jhp21* promoter (Zhang *et al*., 1996). After transcription was found to be specific for the reproductive female fat body, truncated constructs of the promoter region of the *jhp21* gene were used to show that the DNA between nucleotides −1056 and −1200 from the transcription start site strongly enhanced transcription. In synthetic constructs, the incorporation of two tandem copies of the 15 nucleotide element GAGGTTCGAGACCTC (found at −1152) stimulated transcription as strongly as the native 145 nucleotide sequence, whereas the 15 nucleotide element, mutated at four positions and inserted into two copies, was inactive (Zhang *et al*., 1996). These results suggested that the sequence GAGGTTCGAGACCTC might be a JH response element. Tests of nuclear extracts for specific protein binding to the putative JH response element with the electrophoretic mobility shift assay demonstrated the occurrence of a specific DNA binding protein in extracts from JH exposed fat body, whereas it was found to be lacking in JH deprived tissue (Zhang *et al*., 1996). Furthermore, Zhou *et al*. (2002) have reported that this binding shows a preference for the inverted repeat GAGGTTC in the left half-site and that it is abolished by phosphorylation catalyzed by a protein kinase C present in the nuclear extracts. These results further support the identification of a putative JH response element that is bound by a transcription factor brought to an active state by JH. It is still uncertain whether the binding protein may be the nuclear JH receptor, a dimerization partner of the receptor, or another protein factor involved in the transcriptional process (Wyatt, 1997).

A putative JH response element has been identified in the JH esterase gene (*Cfjhe*) from the spruce budworm, *C. fumiferana* (Kethidi *et al*., 2004). This 30 bp region contains two conserved hormone response element half-sites separated by a 4 nucleotide spacer similar to the direct repeat 4 (DR-4). The response element designated as JHRE is located between −604 and −574 of the *Cfjhe* promoter and is sufficient to support JH I induction. At the same time, the same region is responsive for 20E mediated repression of this gene. When a luciferase reporter was placed under the control of JHRE, a minimal promoter was induced by JH I in a dose and time dependent manner in a cell transfection assay. Moreover, the gel-retardation assay revealed the presence of a JHRE binding protein in the nuclear extract isolated from JH I treated CF-203 cells. The results described in the following sections suggest the hypothesis that JH acts via a nuclear receptor mode of action at the transcriptional level.

3.9.2.3.4. Is there a juvenile hormone nuclear receptor? Early experiments studying farnesol related molecules as possible ligands for the retinoid x receptor (RXR)–FXR mammalian receptor complex showed that JH III activated this complex (although it did not activate FXR or RXR alone), whereas methoprene did not (Forman *et al*., 1995). Curiously enough, an independent study reported that RXR alone could be activated by methoprene acid but not by JH III (Harmon *et al*., 1995). Although the physiological significance of these experiments remained unclear, attention has been drawn to *Ultraspiracle* (USP) (insect ortholog of RXR and obligatory dimerization partner for the EcR) as a possible candidate for a JH receptor.

Work along this line was published by Jones and Sharp (1997), who reported that JH at micromolar concentrations binds to *D. melanogaster* USP, modifying its conformation and inducing USP dependent transcription, whereas yeast two-hybrid assays indicated that JH could promote USP homodimerization (see **Chapters 3.5** and **3.7**). In response to ligand binding, *D. melanogaster* USP undergoes

conformational change to form a multihelix hydrophobic groove for recruitment of transcriptional coactivators (Jones and Jones, 2000). In addition, JH III binds to the ligand binding pocket of USP, and application of JH III to cells activates a transfected reporter construct containing a JH esterase core promoter and a DR12 hormone response element. The DR12 element confers enhanced transcriptional JH responsiveness, and it binds with specificity to recombinant USP (Jones *et al*., 2001; Xu *et al*., 2002).

In more primitive insects, USP has a ligand binding domain closer to vertebrate RXR than to dipteran or lepidopteran USP (Bonneton *et al*., 2003). This has raised the question of whether an RXR ortholog of primitive insects might bind JH with higher affinity than USPs of higher insects. This possibility has been explored in *L. migratoria*, in which two isoforms of RXR are known: LmRXR-L is more closely related to vertebrate RXR and LmRXR-S has a deletion of 66 nucleotides in the ligand binding domain (Hayward *et al*., 2003). Both LmRXR-S and LmRXR-L formed heterodimers with locust LmEcR *in vitro*, which bound the active ecdysteroid ponasterone A, as expected. However, neither LmRXR isoform alone nor LmRXR heterodimerizing with LmEcR bound JH III at nanomolar concentrations (Hayward *et al*., 2003). Parallel work in *B. germanica* has led to cloning of the orthologs BgRXR-L and BgRXR-S. Interestingly, despite the highly fluctuating levels of circulating JH III, mRNA levels of both BgRXR-L and BgRXR-S isoforms in the fat body remain constant throughout the vitellogenic cycle (Maestro, Martin and Belles, unpublished data).

If either insect USP or RXR is a JH receptor, it behaves in a very different way to other members of the steroid/thyroid hormone nuclear receptor family, especially since its binding of JH is not saturable and is of relatively low affinity. One possibility is that USP or RXR form a heterodimer with a nuclear receptor other than EcR and that this complex might play the role of a JH receptor. Another possibility is inspired by promiscuous nuclear receptors like RXR, PPAR, or PXR of vertebrates (Harmon *et al*., 1995; Zomer *et al*., 2000; Watkins *et al*., 2001), which are activated by a variety of effectors and have K_d values in the micromolar range. These nuclear receptors have been considered as chemical sensors rather than canonical specific receptors (Watkins *et al*., 2001), a concept that could be extended to the interaction of JHs with the RXR/USP of insects.

The *Methoprene resistant* (*Met*) gene of *Drosophila* may also be a useful model for gaining insight into the molecular action of JH. Mutant *D. melanogaster* resistant to methoprene were generated in the 1980s, and these *Met* mutants were also highly resistant to JH III, JH bisexpoxide (JHB_3), and other JHAs, but not to conventional insecticides. Biochemical work later showed the presence of an 85 kDa protein in various tissues of wild-type *D. melanogaster* that bound specifically to JH III with high affinity ($K_d = 6.7$ nM), whereas in *Met* mutants the affinity of this protein for the hormone was lower by six-fold. In addition, JH III stimulation of protein synthesis in male accessory glands was clearly less pronounced in *Met* mutants than in wild-type flies, which suggested that *Met* is involved in the mechanism of action of JH (Shemshedini and Wilson, 1990; Shemshedini *et al*., 1990; see **Chapter 3.7**). Sequencing of the corresponding gene showed that *Met* is a member of the bHLH-PAS family of proteins that behave as transcriptional regulators (Ashok *et al*., 1998). These proteins show a basic helix–loop–helix domain (bHLH), which is characteristic of a number of transcription factors, and a PAS domain, named after the first members of the family: the products of the genes *period* (*Per*) (see **Chapter 4.11**) and *single-minded* (*Sim*) from *D. melanogaster*, and the aryl hydrocarbon receptor (AhR) and the Ah receptor nuclear translocator (ARNT) from vertebrates. Interestingly, *Per* and *Sim* have dimerization partners but no known ligands. AhR and ARNT form a functional dimer in the presence of a ligand, which upregulates a series of genes, the products of which metabolize foreign chemicals. Although *Met* mutants show no serious problems during embryonic and larval development or during metamorphosis (Wilson and Ashok, 1998), it is tempting to consider that the *Met* product could be involved in the transcription of JH-target genes, either by being the JH receptor or a transcription factor of the cascade triggered by JH.

These results also support the hypothesis that *Met* could be a receptor coactivator for the JH receptor, playing a role similar to that reported for the steroid hormone coactivator-1, the disruption of which results in hormone resistance in mice (Xu *et al*., 1998). In this context, it is worth noting that the steroid hormone coactivator-1 also belongs to the bHLH-PAS family and that it and *Met* have the LXXLL motif, which in vertebrate transcriptional activators is needed for binding to nuclear receptors.

The identification of JH response elements in JH responsive genes might be the most promising approach to the characterization of the JH receptor. This strategy is being followed for the *jhp21* gene in *L. migratoria* and for the *cfjhe* gene in

C. fumiferana, with the encouraging results described above. Also promising has been the discovery of JH responsive genes in *D. melanogaster*, such as *JhI-1*, *JhI-21*, *JhI-26*, and *minidiscs* (*mnd*) (Dubrovsky, 2002), whose promoter regions may provide the needed JH response elements more easily, given the genetic, conceptual, and technical background available in studies of this fly. Along this line, promoter regions of the *JhI-26* and *mnd* genes, which are directly inducible by JH, have already been tested for their ability to confer JH inducibility on heterologous reporter genes transfected to S2 cells. Constructs prepared with a 3 kb fragment from a region upstream of either the *JhI-26* or the *mnd* transcription initiation site cloned in front of the *hsp70-lacZ* reporter gene have served for the first experiments. After transfection and methoprene induction, the *JhI-26* promoter insertion conferred between a 6- and 15-fold increase in the 8-galactosidase activity, whereas that of *mnd* conferred between a three- and fourfold increase (Dubrovsky, 2002). The results suggest that these 3 kb promoter fragments contain JH response elements, and thus further study of shorter fragments should lead to the determination of their role. In the meantime, *in silico* studies on the promoter fragments used in the transfections have revealed several motifs showing a significant similarity with the estrogen response element (ERE), suggesting that they can be considered putative response elements (Dubrovsky, 2002).

3.9.2.4. Molecular Mechanisms of Ecdysteroid Action in Vitellogenesis

The early 20E-inducible gene *E75* has been implicated in the JH signaling pathway (Dubrovsky *et al.*, 2004). JH induces the E75A orphan nuclear receptor in *D. melanogaster.* The induction by JH is rapid and does not require protein synthesis, indicating direct action of JH on the *E75* gene. *E75A* mRNA is reduced in ovaries of *apterous*[4] *Drosophila* mutant adults defective in JH secretion. However, *E75A* mRNA expression can be rescued by topical JH analog application. Furthermore, ectopic expression of E75A is sufficient to perform several functions of the JH signaling pathway. Ectopic E75 can downregulate its own transcription and potentiate the JH inducibility in the JH gene, *JhI-21*. In the presence of JH, E75A can also repress 20E activation of early genes including *Broad*. The occurrence of a putative response element for E75 (the motif TGACCAAATT) (Belles, 2004) in the promoter region of the Vg gene of *B. germanica*, led to clone the three isoforms of this transcription factor, BgE75A, BgE75B, and BgE75C, in this cockroach. The pattern of expression of the three isoforms and results of RNAi experiments suggest that JH enhances E75 induction by 20E and that E75 is involved in the modulation of the cycles of oocyte maturation in *B. germanica* (D. Mañé, D. Martin and X. Belles, unpublished).

In contrast to JH, the molecular mechanisms governing 20E regulation of reproductive events have been elucidated in detail for the yellow fever mosquito, *A. aegypti*, and the fruit fly, *D. melanogaster* (see **Chapters 3.5** and **3.6**). Owing to variations in their reproductive biology, studies of these insects often cover different events in female reproductive endocrinology, thus providing complementary information.

3.9.2.4.1. Genetic regulation of ecdysteroid response Ashburner *et al.* (1974) proposed a hierarchical model for the genetic regulation of polytene chromosome puffing by 20E (see **Chapter 3.5**). According to this model, the binding of 20E to its cognate receptor triggers the expression of a small set of early genes, which in turn activate expression of a large set of late genes and which, meanwhile, repress their own transcription. Subsequent genetic and molecular biological studies have revealed events underlying this ecdysteroid regulatory hierarchy in *D. melanogaster* (Thummel, 1996, 2002; Bender, 2003). Responses to ecdysteroids are mediated by the EcR complex, which consists of two members of the nuclear receptor gene family, EcR and USP, the latter being the retinoid X receptor homolog (Koelle *et al.*, 1991; Yao *et al.*, 1992, 1993). Upon binding 20E, this heterodimer recognizes a sequence specific DNA motif, ecdysteroid response element (EcRE), and directly induces the transcription of a small set of so-called early genes. These early genes encode mainly transcription factors, including E74, E75, and Broad-Complex (BR-C), of the Ets, nuclear receptor, and zinc-finger type, respectively, that transfer and amplify the hormonal signal through the regulation of numerous late ecdysone-responsive genes that specify stage and tissue specific effects of 20E (Thummel, 1996, 2002). The *E74*, *E75*, and *BR-C* early genes each encode a family of transcription factors by use of multiple promoters and alternative splicing. Biochemical and mutational analysis has shown that each of these genes acts as a 20E induced transcription factor and is required for the hormonal response in target tissues (Thummel, 2002; Bender, 2003).

3.9.2.4.2. Ecdysteroid receptor (EcR) The diversity of cellular responses to 20E may require particular combinations of EcR isoforms. Indeed,

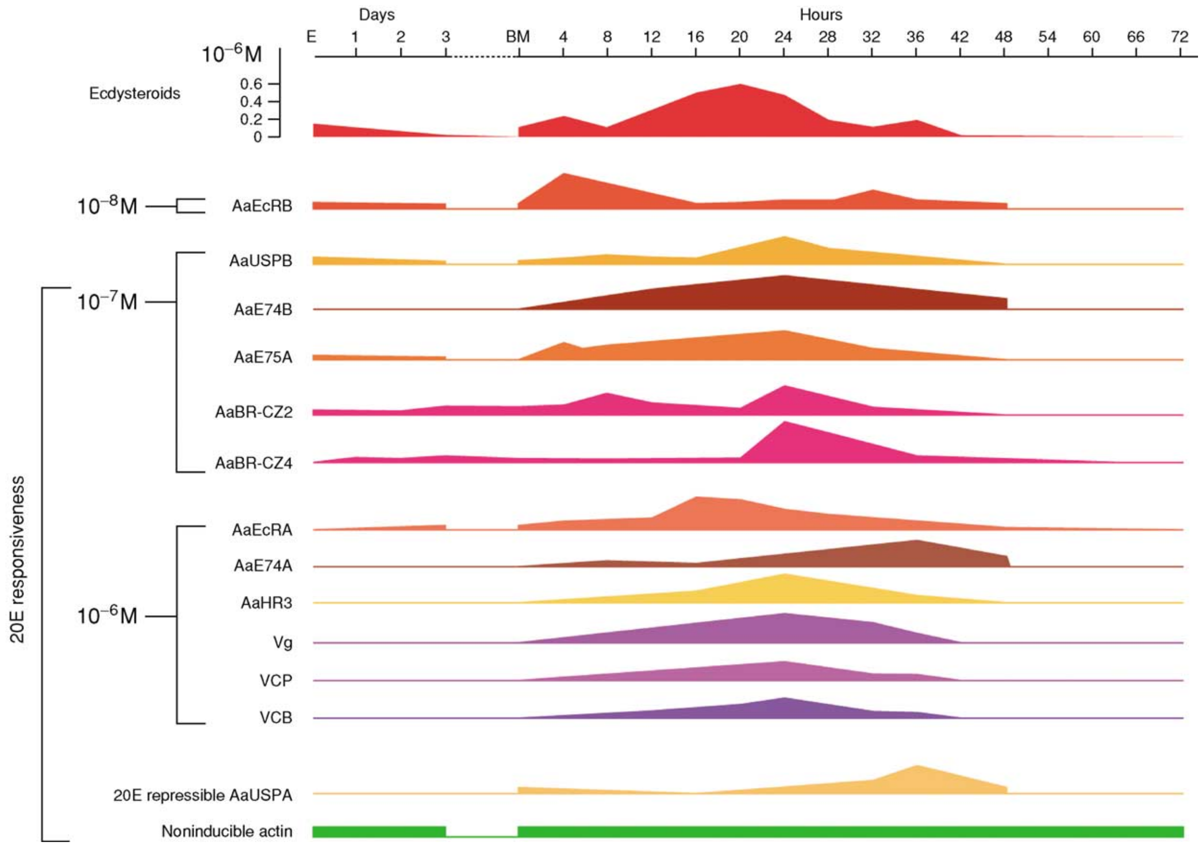

Figure 9 Expression profiles and hormone responsiveness of the key factors of the 20-hydroxyecdysone (20E) regulatory hierarchy and their target genes, yolk protein precursors (*YPP*), during vitellogenesis in *Aedes aegypti*. Hormone titers of 20E in *A. aegypti* females (Hagedorn *et al.*, 1975; Shapiro *et al.*, 1986). Transcript profiles and sensitivities of the transcription factors to 20E (AaEcRA and AaEcRB, AaUSPA and AaUSPB, AaE74A and AaE74B, and AaHR3) and the late genes (*Vg*, *VCP,* and *VCB*) were determined by Northern or RT-PCR analyses. Adapted from Cho and Raikhel (1992; *Vg*), Cho *et al.* (1991; *VCP*), Cho *et al.* (1999; *VCB*), Wang *et al.* (2002; AaEcRA and AaEcRB), Wang *et al.* (2000b; AaUSPB and the 20E repressible AaUSPA), Sun *et al.* (2002; AaE74A and AaE74B), Pierceall *et al.* (1999; AaE75A), Kapitskaya *et al.* (2000; AaHR3), and L. Chen, J. Zhu, and A.S. Raikhel (unpublished data; BR-C isoforms Z2 and Z4). E, eclosion; BM, blood meal. (Modified with permission from Sun, G.Q., Zhu, J.S., Raikhel, A.S., **2004**. The early gene E74B isoform is a transcriptional activator of the ecdysteriod regulatory hierarchy in mosquito vitellogenesis. *Mol. Cell. Endocrinol. 218*, 95–105.)

expression of specific *D. melanogaster* EcR isoforms could be correlated with patterns of responses of particular cell or tissue types to 20E (Talbot *et al.*, 1993). Genetic studies have confirmed that different EcR proteins are functionally distinct, with the greatest difference being between the EcR-A and EcR-B isoforms and the greatest overlap being between the EcR-B1 and EcR-B2 functions (Bender *et al.*, 1997; Schubiger *et al.*, 1998; Lee *et al.*, 2000; see **Chapter 3.5**).

Cloning of the *A. aegypti* EcR isoforms, AaEcR-A and AaEcR-B, has facilitated evaluation of their expression during mosquito vitellogenesis. Significantly, transcripts of both isoforms exhibit different patterns of expression after a blood meal triggers fat body vitellogenesis in female mosquitos (**Figure 9**). The AaEcR-B transcript level rose sharply by 4 h PBM, which coincides with the small ecdysteroid peak, and then declined and reached its lowest level at 16–24 h PBM. In contrast, the AaEcR-A transcript peaked at 16–20 h PBM, coinciding with the large ecdysteroid peak (Cho *et al.*, 1995; Wang *et al.*, 2002). Both isoform mRNAs were transcribed in a cycloheximide independent manner, suggesting that they are direct targets of 20E. However, AaEcR-A transcription requires the continuous presence of 20E, while the AaEcR-B mRNA level rose for 4 h and then declined under the same conditions. These results indicate that the mosquito EcR isoforms play distinct physiological functions during vitellogenesis in the mosquito fat body.

3.9.2.4.3. USP isoforms Like the EcR isoforms, two USP cDNA isoforms (AaUSP-A and AaUSP-B) were cloned from *A. aegpyti* (Kapitskaya *et al.*, 1996). They differ only at the N-terminus, thus

indicating their origin from the same gene, which recently has been confirmed by cloning the *USP* gene from *A. aegypti* (Wang, Zhu, and Raikhel, unpublished data). The isoform specific expression patterns in the *Aedes* fat body during vitellogenesis suggest that the two mosquito USP isoforms may carry out distinct functions. The level of AaUSP-B mRNA correlates with the high titer of ecdysteroid at 16–20 h PBM (Wang *et al*., 2000b). Intriguingly, USP-B is activated with 20E, whereas USP-A is inhibited by the hormone (**Figure 9**) (Wang *et al*., 2000b). AaEcR heterodimerizes with either mosquito USP isoform; the AaEcR-USP-B heterodimer displays stronger DNA binding and transactivation activities than the AaEcR-USP-A heterodimer (Wang *et al*., 2000b).

3.9.2.4.4. Ecdysteroid response elements (EcREs) The canonical steroid receptor binding site is a DNA element with an AGGTCA consensus sequence that binds one or two receptor molecules as monomers or as homodimers and/or heterodimers (Tsai and O'Malley, 1994). The binding sites can be arranged as single half sites or as inverted, direct, or everted repeats. Although DNA binding by EcR-USP is highly sequence specific, a surprising variety of sequences have been identified as ecdysteroid response elements in *D. melanogaster* (see **Chapter 3.5**), suggesting that variability of EcREs provides yet another level of specificity in 20E gene regulation (Riddihough and Pelham, 1987; Cherbas *et al*., 1991; Antoniewski *et al*., 1994, 1995, 1996; D'Avino *et al*., 1995; Horner *et al*., 1995; Lehmann and Korge, 1995).

The DNA binding properties of the AaEcR-AaUSP heterodimer have been systematically analyzed with respect to the effects of nucleotide sequence, orientation, and spacing between half sites in natural *D. melanogaster* and synthetic EcREs (Wang *et al*., 1998). AaEcR-AaUSP exhibits a broad binding specificity, forming complexes with inverted repeats (IRs) and direct repeats (DRs) of the nuclear receptor response element half-site consensus sequence AGGTCA separated by spacers of varying length. A single nucleotide spacer was optimal for both imperfect (IR^{hsp}-1) and perfect (IR^{per}-1) inverted repeats. Spacer length was less important in DRs of AGGTCA (DR-0 to DR-5). Although 4 bp was optimal, DR-3 and DR-5 bound AaEcR-AaUSP almost as efficiently as DR-4. Furthermore, AaEcR-AaUSP also bound DRs separated by 11–13 nucleotide spacers. Cotransfection assays utilizing CV-1 cells have demonstrated that the mosquito EcR-USP heterodimer is capable of transactivating reporter constructs containing either IR-1 or DR-4. The levels of transactivation are correlated with the respective binding affinities of the response elements (IR^{per}-1 > DR-4 > IR^{hsp}-1). Taken together, these analyses predict broad variability in the EcREs of mosquito ecdysteroid responsive genes (Wang *et al*., 1998). These analyses enabled the identification of a functionally active EcRE that binds the heterodimer EcR-USP in the *A. aegypti Vg* gene. A direct repeat with a 1 bp spacer (DR-1) with the sequence AGGCCAaTGGTCG is the major part of the EcRE in the *Vg* gene (Martin *et al*., 2001a).

3.9.2.4.5. Ecdysteroid early response genes The *A. aegypti E75* homolog consists of three overlapping transcription units encoding E75A, E75B, and E75C isoforms (Pierceall *et al*., 1999), which are members of the nuclear receptor family. As in *D. melanogaster*, these E75 transcripts arise by alternative promoter usage and splicing of transcription unit-specific 5′ exons onto a set of shared downstream exons. All three transcripts are induced at the onset of vitellogenesis by a blood meal and are highly expressed in the mosquito ovary and fat body, which suggests that they are involved in the regulation of oogenesis and vitellogenesis, respectively. Furthermore, *in vitro* fat body experiments have demonstrated that AaE75 isoforms are induced by 20E. In contrast to the yolk protein transcripts, which show only a small gradual increase during the first 4 h PBM, E75 transcripts exhibit a sharp rise immediately after the onset of vitellogenesis, reaching a peak at 3–4 h PBM, when the hormone titer shows a first peak. After falling from their initial peak, the level of mosquito E75 transcripts gradually increase again, reaching the second peak at 18–24 h PBM, which coincides with the accumulation of yolk protein RNA in the fat body (**Figure 9**). E75 isoform transcription is appropriately 10 times more sensitive to 20E than is the *Vg* gene (Pierceall *et al*., 1999).

Two isoforms of the homolog to the *D. melanogaster* transcription factor E74, which share a common C-terminal Ets DNA binding domain, yet have unique N-terminal sequences, are present in the mosquito. They exhibit a high level of similarity to DmE74 isoforms A and B and show structural features typical for members of the Ets transcription factor superfamily (Sun *et al*., 2002). Furthermore, both mosquito E74 isoforms bind to a *D. melanogaster* E74 binding site with the consensus motif C/AGGAA. E74B mRNA reaches its peak at 24 h PBM and drops sharply thereafter, correlating with peak expression of the *Vg* gene. The AaE74B transcript is induced by a blood meal activated hormonal cascade in fat body and peaks at 24 h PBM, the peak of

vitellogenesis (**Figure 9**). However, unlike E75 transcripts, E74B does not have an early peak at 3–4 h. AaE74A is activated at the termination of vitellogenesis and exhibits a peak at 36 h PBM in the fat body and 48 h PBM in the ovary. The AaE74A and AaE74B isoforms most likely play different roles in regulation of vitellogenesis in mosquitos, as an activator and a repressor of YPP gene expression, respectively. Both AaE74 isoform mRNAs are induced by 20E in fat body *in vitro* and display superinduction when cycloheximide is applied together with 20E (Sun *et al*., 2004). While both E74 isoforms are capable of binding to the E74 consensus sequence, only E74B induces a reporter gene expression through the consensus E74 binding site in cell transfection assays. Furthermore, a transient transfection assay using the *Vg* promoter region containing putative E74 binding sites has shown that E74B functions as an activator, whereas E74A serves as a repressor (Sun *et al*., 2004).

The BR-C plays a key role in the genetic control of 20E responses. The BR-C encodes a family of DNA binding proteins that share a common (core) N-terminus fused by alternative splicing to one of four pairs of C2H2-type zinc finger domains, Z1, Z2, Z3, and Z4. All four BR-C isoforms are present in *A. aegypti* (Chen, Zhu, and Raikhel, unpublished data). In female fat body, expression of Z1, Z2, and Z4 is induced immediately after a blood meal. Both Z1 and Z4 transcripts exhibit a peak at 24 h PBM. The Z2 transcript exhibits a sharp increase after onset of vitellogenesis, reaching initial peak at 8 h PBM. After an initial decline, the level of Z2 rises again at 24 h PBM (**Figure 9**). The expression of BR-C Z1, Z2, and Z4 in the fat body is attenuated between 24 h and 36 h PBM. Z3 transcript expression in the fat body is very low throughout the vitellogenic cycle. The overall level of Z4 has been found to be much higher than those of the other isoforms. In the fat body *in vitro* experiments, the mRNA levels of all four isoforms were rapidly induced by 20E and increased in a dose dependent manner. Functional analysis using RNAi experiments has suggested that Z1 and Z4 serve as repressors and that Z2 serves as an activator of *Vg* gene expression. Remarkably, RNAi knockdown of Z1 or Z4 extends *Vg* expression to 36 h PBM, which suggests that these factors regulate hormone dependent timing of this gene transcription (Chen, Zhu, and Raikhel, unpublished data).

Analyses of 20E sensitivity by transcripts of several key mediators and their expression profiles in vitellogenic fat body of the mosquito have revealed potential roles in the 20E gene regulatory hierarchy cascade, thus providing a road map for future studies (Pierceall *et al*., 1999; Kapitskaya *et al*., 1998; Li *et al*., 2000; Wang *et al*., 2000b, 2002; Sun *et al*., 2002, 2004) (**Figure 9**). At the top of the 20E cascade, AaEcRB, the dominant isoform for initiating mosquito vitellogenesis *in vivo*, exhibits high sensitivity to 20E at 10^{-8} M, and it is expressed predominantly during the first hours after blood meal activation of vitellogenesis (Wang *et al*., 2002) (**Figure 9**). Its obligatory partner AaUSP-B, early gene products AaE74B and AaE75A, and BR-C isoforms constitute the group with the second highest sensitivity to 20E at 10^{-7} M (Pierceall *et al*., 1999; Wang *et al*., 2000; Sun *et al*., 2004; Chen, Zhu, and Raikhel, unpublished data). AaEcR-A, AaE74A, and the early late gene *AaHR3* form the lowest 20E sensitivity group, being maximally activated at 10^{-6} M, which is similar to the target genes *Vg*, *VCP*, and *VCB* (**Figure 9**).

3.9.2.4.6. Hormonal enhancers in the regulatory region of mosquito yolk protein genes Transcriptional activation of hormonally controlled genes in specific tissues depends on interactions between sequence specific transcription factors and enhancer/promoter elements of these genes. Analysis of the 5′-upstream regulatory region of the mosquito *Vg* gene has revealed putative binding sites for EcR-USP and the early genes, E74, E75, and BR-C, which indicate this gene is regulated through a combination of direct and indirect hierarchies (**Figure 10**). Analyses of *D. melanogaster* and *A. aegypti* transformations, as well as DNA binding assays, have identified *cis*-regulatory sites in the *Vg* gene for stage and fat body specific activation via a blood meal triggered cascade (Kokoza *et al*., 2001). Three regulatory regions in the 2.1 kb, 5′ region of the *Vg* gene are required for its blood meal activation and high-level expression (**Figure 11**). The proximal region, adjacent to the basal transcription start site, contains binding sites for several transcription factors that direct tissue and stage specific expression: EcR/USP, GATA transcription factor (GATA), CAAT binding protein (C/EBP), and hepatocyte nuclear factor 3/forkhead transcription factor (HNF3/fkh). It appears that a combinatorial action of these transcription factors brings about fat body specific expression. EcR/USP acts as a timer, allowing the gene to be turned on, but the level of expression driven through this response element is low. The median region contains the sites for early gene factors E74 and E75, and transgenic studies have shown that this region is required for a stage specific hormonal enhancement of the *Vg* gene expression

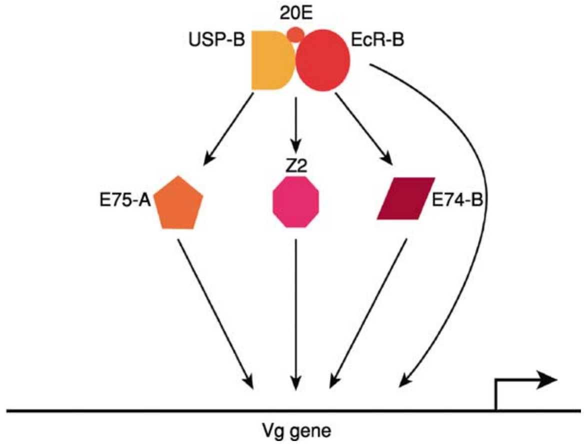

Figure 10 Direct and indirect regulation of vitellogenin (*Vg*) gene by 20-hydroxyecdysone in the mosquito fat body. The activated ecdysteroid receptor, consisting of EcR-B/USP-B binds to the EcRE response element in the regulatory region of the *Vg* gene. This binding is required to permit the *Vg* gene expression. After binding 20E, the EcR-USP heterodimer also activates early genes, *E74, E75*, and *BR-C*. The products of these genes E74-B, E75-A, and BR-C Z2 act as powerful activators of the *Vg* gene. (Based on Pierceall, W.E., Li, C., Biran, A., Miura, K., Raikhel, A.S., *et al.*, **1999**. E75 expression in mosquito ovary and fat body suggests reiterative use of ecdysone-regulated hierarchies in development and reproduction. *Mol. Cell. Endocrinol. 150*, 73–89; Kokoza, V.A., Martin, D., Mienaltowski, M.J., Ahmed, A., Morton, C.M., *et al.*, **2001**. The vitellogenin gene of the mosquito *Aedes aegypti* is a direct target of ecdysteroid receptor. *Mol. Cell. Endocrinol. 173*, 75–86; Sun, G.Q., Zhu, J.S., Li, C., Tu, Z.J., Raikhel, A.S., **2002**. Two isoforms of the early E74 gene, an Ets transcription factor homologue, are implicated in the ecdysteroid hierarchy governing vitellogenesis of the mosquito, *Aedes aegypti*. *Mol. Cell. Endocrinol. 190*, 147–157; L. Chen, J. Zhu, and A.S. Raikhel, unpublished data.)

(Kokoza *et al*., 2001). Furthermore, *in vitro* cell transfection experiments have demonstrated that the ecdysteroid receptor and E74B act synergistically to bring about a high-level, 20E activated *Vg* gene expression (Sun and Raikhel, unpublished data). Finally, the distal portion is characterized by multiple response elements for a GATA transcription factor (Martin *et al*., 2001b). In transgenic experiments using both *A. aegypti* and *D. melanoagaster*, this GATA- rich region is required for high expression levels characteristic to the *Vg* gene (**Figure 11**).

Recent analyses of the *A. aegypti Vg* promoter region have identified many binding sites for the BR-C transcription factors: one for Z1, two for Z2, three for Z3, and seven for Z4. When BR-C isoform expression vectors were introduced into Kc cells together with EcR and USP expression vectors in the presence of 20E, Z1 and Z4 repressed the activation mediated by EcR-USP, while Z2 enhanced this activation. The role of Z3 was negligible. When the Z1 binding site was mutated, luciferase activity driven by the *Vg* promoter was no longer inhibited by the overexpression of Z1. After removal of Z2 binding sites in the *Vg* promoter, Z2 lost the capability to increase luciferase activity. However, because there are seven binding sites of BR-C Z4 on the *Vg* promoter, the repression of *Vg* promoter by Z4 could not be completely released after mutation of all the Z4 binding sites. These experiments support the RNAi test performed *in vivo* and suggest that BR-C Z1 and Z4 serve as repressors while Z2 is an activator of the *Vg* gene expression. Z4 may not directly bind to the *Vg* promoter (Chen, Zhu, and Raikhel, unpublished data).

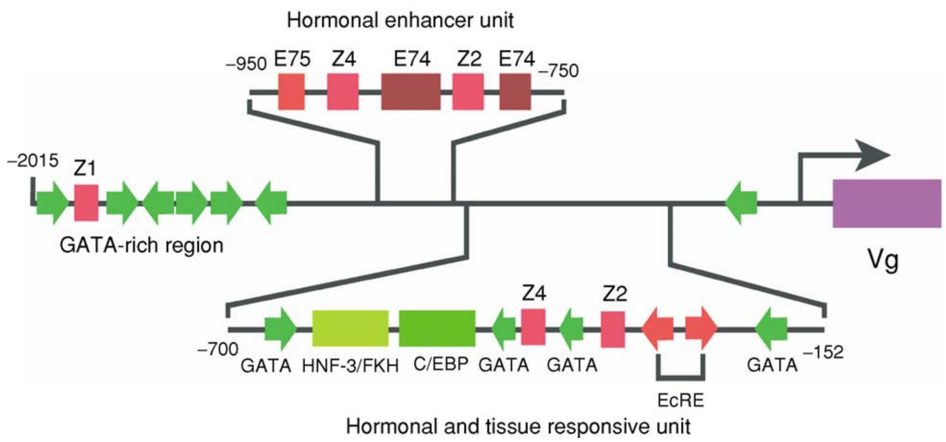

Figure 11 Schematic illustration of the regulatory regions of the *Aedes aegypti Vg* gene. Numbers refer to nucleotide positions relative to the transcription start site. Binding sites for hormonal transcription factors are depicted in red and those for tissue specific factors in green. C/EBP, response element of C/EBP transcription factor; EcRE, ecdysteroid response element; E74 and E75, response elements for respective early gene product of the ecdysone hierarchy; GATA, response element for GATA transcription factor; HNF3/fkh, response element for HNF3/forkhead factor; Vg (purple), coding region of the *Vg* gene; Z1, Z2, and Z4 are binding sites for corresponding Broad-Complex isoforms. 3.9.2.4.7. Competence to 20E response Female mosquitos, such as *A. aegypti*, require a previtellogenic preparatory period to attain the capability for host seeking behavior and blood feeding. During this time, the fat body becomes competent for massive yolk protein synthesis and secretion, and the ovary for accumulation of YPs. In the fat body, this process is manifested in the development of the endoplasmic reticulum and Golgi complexes, proliferation of ribosomes, and increase in cell ploidy (Dittmann *et al*., 1989; Raikhel and Lea, 1990). JH III titers rise tenfold over the first 2 days after emergence and then slowly decline over the next 5 days. Blood ingestion causes an immediate decline of JH, which falls to its lowest level at 24 h PBM (Shapiro *et al*., 1986). Activation of fat body nucleoli for ribosomal RNA production and ribosomal production is blocked by removal of the CA in newly eclosed adult females, but it can be restored by either implantation of CA or topical application of JH III to allatectomized females. These developmental events most likely are controlled by JH from the CA (Raikhel and Lea, 1990, 1991). The exposure of a newly emerged female mosquito to JH III is essential for the fat body to become responsive to 20E (Flanagan *et al*., 1977; Li *et al*., 2000; Zhu *et al*., 2003a).

To dissect the molecular mechanism governing the acquisition of competence for vitellogenesis in the *A. aegypti* fat body, the mosquito homolog of the ecdysteroid response competence factor, βFTZ-F1, in *D. melanogaster* has been cloned (Li *et al*., 2000). During metamorphosis in *D. melanogaster*, the stage specificity of the genetic response to 20E is set up by βFTZ-F1, an orphan nuclear receptor. Ectopic *βFTZ-F1* expression leads to elevated transcription levels for 20E-inducible *BR-C* and the early genes *E74* and *E75*. *βFTZ-F1* mutants pupate normally in response to the late larval 20E pulse but display defects in stage specific responses to the subsequent 20E pulse in prepupae (Lam *et al*., 1997; White *et al*., 1997). Mosquito *βFTZ-F1* is transcribed highly in the late pupa and in the adult female fat body during pre- and postvitellogenic periods, when ecdysteroid titers are low, and the transcripts nearly disappear in midvitellogenesis, when ecdysteroid titers are high. Each rise in the level of *βFTZ-F1* transcripts is preceded by a high expression of another nuclear receptor (HR3) that coincides with the 20E peaks (Kapitskaya *et al*., 2000; Li *et al*., 2000). This observation is consistent with the role of *HR3* in *D. melanogaster*, which facilitates induction of *βFTZ-F1* in mid-prepupa.

Although the genetic tools are limited for the *A. aegypti*, experiments with the fat body *in vitro* lend support at the functional level to the hypothesis that FTZ-F1 serves as a competence factor for the ecdysteroid response initiating vitellogenesis. In these experiments, FTZ-F1 transcription is inhibited by 20E and is superactivated by its withdrawal (Li *et al*., 2000). Electrophoretic mobility-shift assay analysis of nuclear extracts from *A. aegypti* fat body demonstrated that the onset of ecdysone response competence in this tissue is correlated with the appearance of the functional FTZ-F1 protein at the end of previtellogenic development (Li *et al*., 2000). Western blot analysis using antibodies to *A. aegypti* βFTZ-F1 show that the βFTZ-F1 protein is not detectable in the fat body nuclear extracts of newly emerged and 1-day-old mosquitos but is abundant at 3–5 days posteclosion (PE), and then not dectected shortly after blood feeding (Zhu *et al*., 2003a). Furthermore, when fat body from females was isolated at 6 h PE and incubated for 18 h in medium with JH III, the nuclei contained βFTZ-F1 protein, in contrast to controls incubated with acetone (Zhu *et al*., 2003a). Taken together, these findings indicate that JH III is quite likely the crucial factor modulating production of βFTZ-F1 protein in the fat body through posttranscriptional regulation of its gene in the previtellogenic stage (**Figure 12**).

To confirm that *βFTZ-F1* may encode a competence factor in the fat body of female *A. aegypti*, it was silenced by RNAi, which involves the introduction of homologous double-stranded RNA (dsRNA) in order to target specific mRNAs for degradation (Zhu *et al*., 2003a). Compared with naïve females, the mRNA and protein levels of *βFTZ-F1* declined substantially in females treated with *βFTZ-F1* dsRNA but not in those treated with control dsRNA, which indicates that *βFTZ-F1* was selectively inhibited by RNAi. Expression of the *Vg* gene was dramatically diminished after blood feeding in the *βFTZ-F1* dsRNA treated mosquitos. These results suggest that *A. aegypti* βFTZ-F1 is essential for the stage specific 20E response in fat body during vitellogenesis, which is reminiscent of the role βFTZ-F1 plays in *D. melanogaster* during the prepupa to pupa transition. Functional analysis of *βFTZ-F1* by the RNAi technique suggests that βFTZ-F1 is in fact a competence factor that defines the stage specific 20E response during vitellogenesis in the mosquito (Zhu *et al*., 2003a).

Despite extensive studies, the mode of JH action is still not well understood. During previtellogenic development in female mosquitos, JH controls the synthesis of βFTZ-F1 protein, but this posttranscriptional control of gene expression can occur at one or more levels: pre-mRNA splicing pattern, mRNA

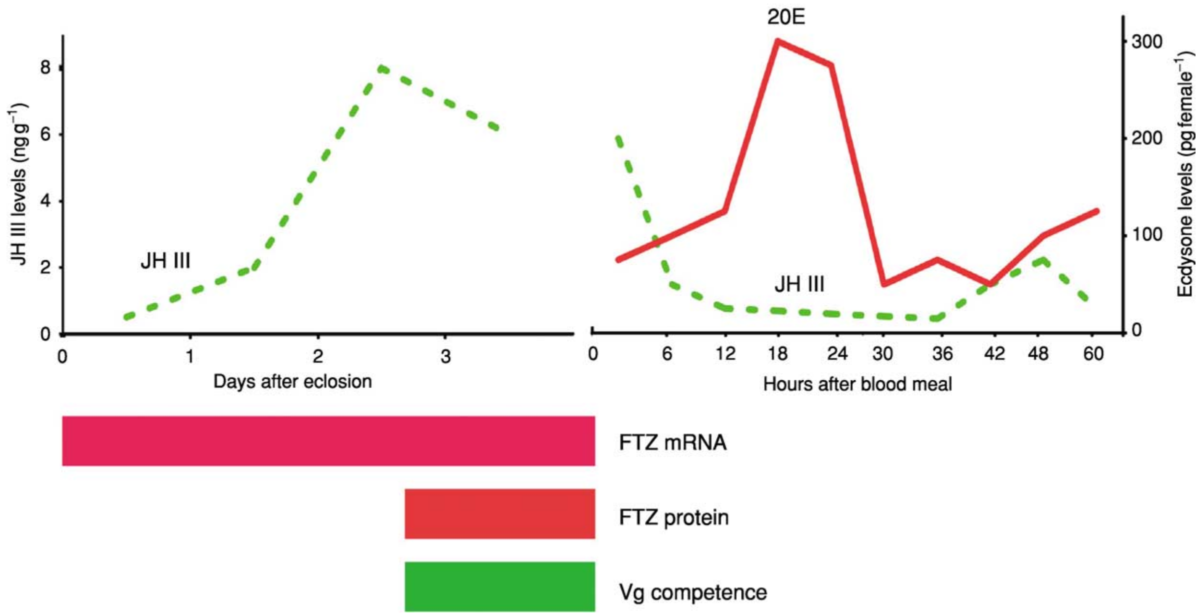

Figure 12 βFTZ-F1, the orphan nuclear factor (see **Chapter 3.5**), is implicated as a competence factor for stage specific response to ecdysteroid during vitellogenesis in the *Aedes aegypti* fat body. The *AaFTZ-F1* mRNA is present at late pupal and previtellogenic stages in newly eclosed females; however, the appearance of active AaFTZ-F1 factor coincides with the onset of competence for 20E response (Li *et al.*, 2000; Zhu *et al.*, 2003a). (Reprinted with permission from Raikhel, A.S., Kokoza, V.A., Zhu, J.S., Martin, D., Wang, S.F., *et al.*, **2002**. stability, mRNA transport, or translation rate. Although the mechanism underlying this regulation remains obscure, these findings represent another step towards understanding the mode of JH action.

3.9.2.4.8. Regulation of vitellogenesis cyclicity by ecdysteroid mediated signaling through heterodimerization with the RXR homolog Ultraspiracle In many insects, vitellogenesis and egg maturation arecyclic and, as a consequence, these insects produce batches of eggs, unlike others that lay eggs continuously. Generally, the mode of egg production – continuous or cyclic – depends upon feeding and lifestyle adaptations. Cyclic egg production occurs in all insect genera irrespective of the type of hormonal control. In insects, in which reproduction is governed by JH, these mechanisms are poorly understood at the molecular level. However, for insects with cyclic egg production that depends primarily on ecdysteroids, recent studies of the mosquito, *A. aegypti*, have shed some light on these mechanisms.

Zhu *et al*. (2000, 2003b) and Miura *et al*. (2002) have demonstrated that during mosquito vitellogenesis, two nuclear receptors, HR38 and Svp, regulate the cyclicity of ecdysteroid mediated signaling via heterodimerization with USP. Both AaEcR and AaUSP proteins are abundant in nuclei of the previtellogenic female fat body at the state of arrest; however, the EcR-USP heterodimer capable of binding to the specific ecdysone response elements is barely detectable in these nuclei. Studies have shown that EcR is a primary target of 20E signaling modulation in target tissues at the state of arrest. A possible mechanism through which the formation of ecdysteroid receptor activity can be regulated is a competitive binding of other factors to either EcR or USP. Indeed, at this stage, AaUSP exists as a heterodimer with the orphan nuclear receptor, AHR38. This protein is a homolog of the *D. melanogaster* DHR38 and vertebrate NGFI-B/Nurr1 orphan receptors, and it acts as a repressor by disrupting EcR binding to DNA response elements and by interacting strongly with AaUSP. However, in the presence of 10^{-6} M of 20E, EcR efficiently displaces AHR38 and forms an active heterodimer with USP, as happens after a blood meal (**Figures 13 and 14**).

To regulate cyclicity in egg production, termination of Vg gene expression is needed in female mosquitos, so that egg maturation and deposition can be completed and the arrest stage restored until another blood meal can be obtained. To identify other negative regulators of the AaEcR/AaUSP mediated 20E response during vitellogenesis, a

mosquito homolog (AaSvp) of the vertebrate orphan nuclear receptor, chicken ovalbumin upstream promoter transcription factor (COUP-TF), and *D. melanogaster* Seven-up (Svp) has been cloned (Miura *et al.*, 2002). Coimmunoprecipitation experiments with nuclear extracts (Zhu *et al.*, 2003b) have clearly shown that in the female fat body AaSvp associates only with AaUSP. Furthermore, formation of AaSvp-AaUSP heterodimers occurs in a precise, timely manner at 30–33 h PBM, after the 20E titer declines to the previtellogenic level and when the expression of *YPP* genes, including *Vg*, is terminated (**Figure 13**). *In vitro* experiments have suggested that the declining titer of 20E could be a critical factor facilitating the formation of Svp-USP heterodimers (Zhu *et al.*, 2003a). Mosquito Svp, thus, represses the 20E mediated transactivation of vitellogenesis through its heterodimerization with USP (Zhu *et al.*, 2003b).

The modulation of vitellogenesis cyclicity appears to be regulated through alternative heterodimerization of the RXR homolog USP that blocks ecdysteroid mediated signaling (**Figure 14**). AaUSP exerts its functions by associating with distinct partners at different stages of vitellogenesis. During the arrest stage, AHR38 prevents the formation of the functional EcR complex by sequestering AaUSP, which blocks 20E dependent transactivation. After a blood meal, the AaEcR-AaUSP heterodimerization becomes dominant, and AaEcR-AaUSP binding to EcREs on the Vg gene permits its expression. When vitellogenesis proceeds to the termination stage, falling 20E titers shift AaUSP heterodimerization towards AaSvp, repressing USP-based hormone responses (**Figure 14**).

In summary, these studies clearly show that the cyclicity of vitellogenesis in the mosquito fat body is regulated through USP, which sequentially forms inactive or active heterodimers with either repressors (HR38 and Svp) or the activator (EcR) and directly affects ecdysteroid mediated signaling.

3.9.2.5. Molecular Endocrinology of Vitellogenesis in the Cyclorrhaphan Diptera

3.9.2.5.1. Vitellogenesis and hormones in *D. melanogaster* Like the mosquito, the fat body in fruit flies matures and differentiates at eclosion under the control of JH, but it immediately begins to synthesize YPs and secrete them into the hemolymph. Simultaneously, the uptake of YPs is initiated by developing oocytes that mature into eggs, which are fertilized and laid continuously. If the fly does not mate or has enough food, mature eggs are retained, and oocytes

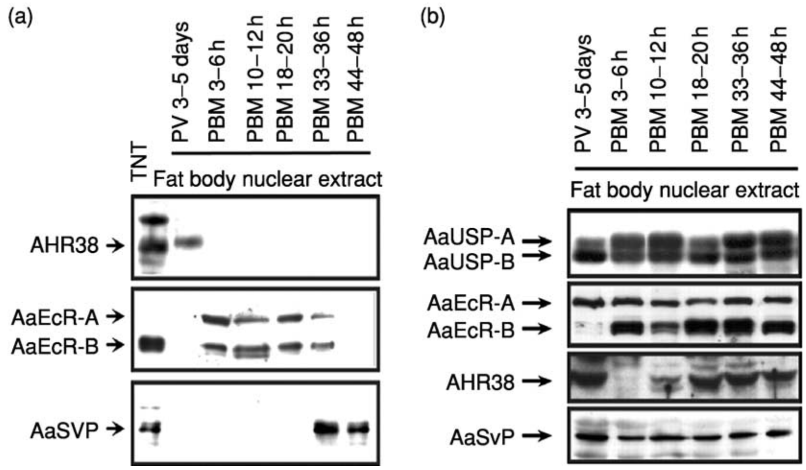

Figure 13 *Aedes aegypti Ultraspiracle* (AaUSP) interacts sequentially with a repressor AHR38, an activator AaEcR, and then with repressor AaSvp in the fat body during the vitellogenic cycle. Nuclear extracts were prepared from the fat bodies of 500 adult females for each time point. (a) Coimmunoprecipitation analysis. A protein aliquot equivalent to 100 mosquitos was incubated with anti-*Drosophila* USP monoclonal antibody. The resulting immune complexes were then precipitated by the addition of protein A-agarose beads. After extensive washing, immune complexes were dissociated and separated by means of SDS-PAGE followed by immunoblotting using rabbit anti-AHR38, rabbit anti-AaEcR, chicken anti-AaSvp antibodies, or the respective preimmune sera. *In vitro* translated proteins (AHR38, AaEcR-B, and AaSvp) were used as controls in Western blot analysis. (b) Western blot analysis of USP proteins during the vitellogenic cycle shows that two isoforms of USP are present throughout the vitellogenic cycle in fat body nuclei. A protein aliquot equivalent to 25 fat bodies was loaded in each lane for SDS-PAGE. Western blot analysis was performed using the anti-DmUSP monoclonal antibody. *In vitro* TNT expressed USP-A and USP-B proteins were used as positive controls. (Reproduced with permission from Zhu, J.S., Miura, K., Chen, L., Raikhel, A.S., **2003b**. Cyclicity of mosquito vitellogenic ecdysteroid-mediated signaling is modulated by alternative dimerization of the RXR homologue *Ultraspiracle*. *Proc. Natl Acad. Sci. USA 100*, 544–549.)

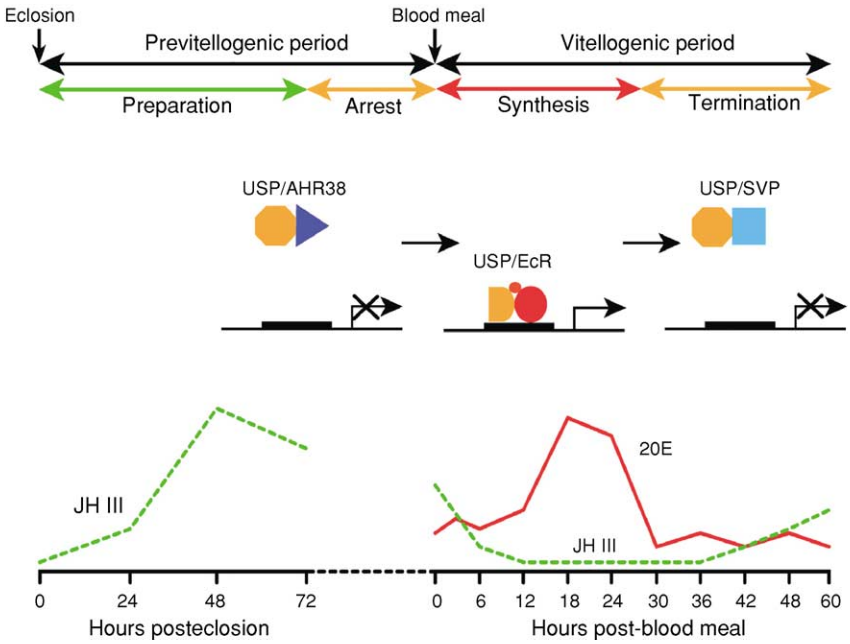

Figure 14 Heterodimerization of *Ultraspiracle* (USP), the obligatory partner of EcR, with repressor nuclear receptors during the first vitellogenic cycle in the mosquito *Aedes aegypti*. At the state of arrest, AaUSP was associated with AHR38, preventing activation of YPP production prior to blood feeding. After a blood meal, AaUSP heterodimerizes with AaEcR, and induces expression of YPP genes in the presence of an elevated 20E titer. Around 30–36 h PBM, AaSvp attaches to AaUSP, decelerating the massive protein synthesis. Top panel: stages of mosquito vitellogenic cycle; bottom panel: titers of juvenile hormone and ecdysteroids. (Modified with permission from Zhu, J.S., Miura, K., Chen, L., Raikhel, A.S., **2003b**. Cyclicity of mosquito vitellogenic ecdysteroid-mediated signaling is modulated by alternative dimerization of the RXR homologue *Ultraspiracle*. *Proc. Natl Acad. Sci. USA 100*, 544–549.)

arrest at a previtellogenic stage and do not enter vitellogenesis (Bownes, personal communication).

Despite the fact that in most cyclorrhaphan Diptera, including *D. melanogaster*, YPs are made in fat body and follicular epithelial cells surrounding the oocyte, the regulation of *yp* gene expression is different in these tissues (Bownes, personal communication). Ecdysteroids stimulate YP synthesis in the fat body of males and upregulate it in the fat body of females (Postlethwait *et al*., 1980; Jowett and Postlethwait, 1980; Bownes, 1982; Bownes *et al*., 1983). This is consistent with the finding that EcREs have been mapped to regions flanking the *yp* genes (Bownes *et al*., 1996). JH also increases YP synthesis in the fat body of females (Bownes and Blair, 1986; Bownes *et al*., 1987; Soller *et al*., 1997), but it does not induce YP synthesis in males. No potential JH elements have been found in these genes. Walker *et al*. (1991) have shown that ecdysteroids increased CAT expression of *YP* promoter CAT fusion in the S3 cell line. JH had no effect on the same reporter construct. Thus, it is unlikely that JH plays any role in directly affecting transcription of *yp* genes in the fat body. JH may play a role in the regulation of yolk protein synthesis by follicle cells, as shown in studies of the *D. melanogaster* mutant ap^{56f} (Richard *et al*., 1998, 2001). Female ap^{56f} produces low levels of JH and normal to elevated levels of ovarian ecdysteroids and are fertile but have delayed vitellogenesis. JH application to female ap^{56f} reversed the delay in vitellogenesis.

Many of the response genes in the ecdysteroid regulatory hierarchy, including *EcR/USP E74, E75*, and *BR-C*, that have been shown to be crucial for 20E regulation of *Vg* gene expression in the fat body of *A. aegypti* have not been studied in *D. melanogaster* with respect to YP synthesis in the fat body. This is mostly because in normal, mated, well-fed females the genes are constitutively active rather than regulated in response to a blood meal (Raikhel *et al*., 2003; Bownes, personal communication).

3.9.2.5.2. Regulatory regions of yolk protein genes in *D. melanogaster* Relatively little is known about the *cis*-acting regions of the *yp* genes in any species of cyclorrhaphan Diptera. Several EcREs have been identified in the 5′ and 3′ regions and within the coding sequences of the *yp* genes of *D. melanogaster* (see **Figures 15 and 16**), and they appear to confer ecdysone inducible expression in males, when injected with 20E. These putative EcRE sequences are similar to those shown to bind the EcRE/USP heterodimer and lead to transcription of other genes in insect metamorphosis and the *Vg*

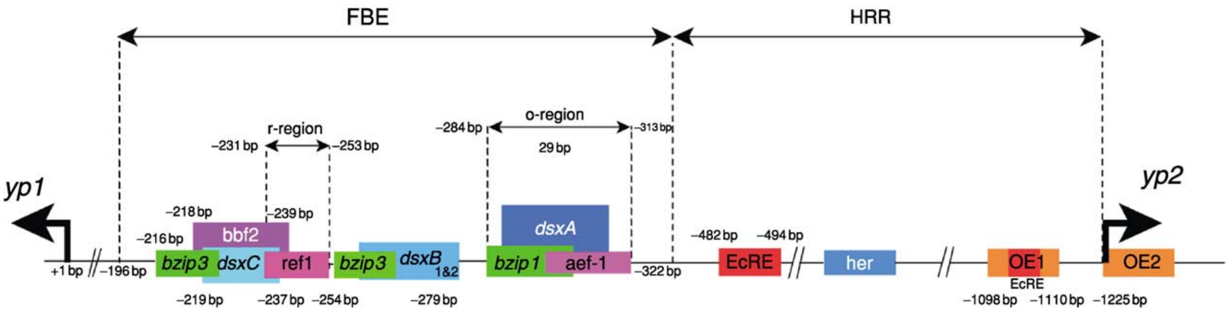

Figure 15 *Drosophila melanogaster yp* genes 1 and 2 are located in close proximity in opposite orientation and share a regulatory region called the intergenic enhancer region. The 1225 bp intergenic enhancer region of the *yp1* and *yp2* genes contains four enhancer regions, the fat body enhancer (FBE), the hermaphrodite response region (HRR), and two ovary enhancers (OE1 and OE2); aef-1, the adult enhancer factor-1; *bzip3*; C/EBP, CAAT enhancer binding protein; *dsx*, doublesex binding site; EcRE, ecdysone response element; her, binding site for the hermaphrodite protein. (Data kindly provided by M. Bownes.)

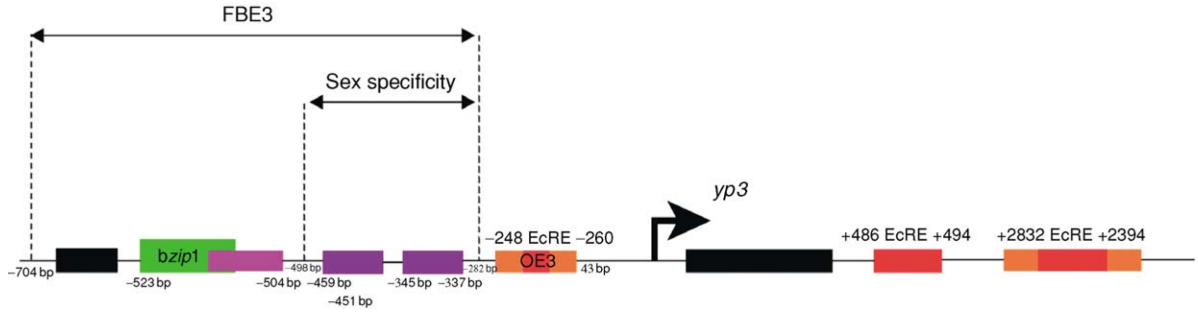

Figure 16 The *Drosophila yp3* gene is separated from two others on the X-chromosome and has a separate regulatory region, the upstream enhancer 3. aef-1, adult enhancer factor 1; bbf, binding site for the box-B binding factor; EcRE, ecdysone response element. (Data kindly provided by M. Bownes.)

genes in the mosquito (Bownes *et al.*, 1996). Although these EcREs have been mapped on the *yp* genes, it is not clear how much of the 20E inducibility of *yp* gene expression is a direct action through the binding of EcR and how much is due to downstream genes such as *BR-C, E74*, and *E75* (Bownes, personal communication).

Despite the fact that the hormonal and molecular control of *yp* gene transcription in *D. melanogaster* is poorly understood, the sex specific expression of these genes has been elucidated in detail (see **Chapters 1.5** and **1.7**). Doublesex (*dsx*) exerts the most important control of *yp* gene expression (Bownes and Nothiger, 1981; Coschigano and Wensink, 1993; Belote *et al.*, 1985). Alternate transcript splicing of *dsx* produces different proteins in male and female adults, Dsx^{M} and Dsx^{F}, respectively, that have similar DNA binding domains but different C-terminal extensions (Baker and Wolfner, 1988; Burtis and Baker, 1989; MacDougall *et al.*, 1995). The male and female proteins are essential for maintaining *yp* transcription in the female fat body and repressing it in males (Bownes and Nothiger, 1981; Belote *et al.*, 1985; Burtis *et al.*, 1991; Bownes, personal communication). In males, 20E injection overrides sex determination inhibition as shown by the transient expression of *yp* genes in the fat body of males (Bownes *et al.*, 1996; Bownes, personal communication). In females, *yp* gene expression in the ovarian follicle cells does not depend upon the sex determination pathway (Logan *et al.*, 1989; Logan and Wensink, 1990; Lossky and Wensink, 1995), and 20E is probably a key hormone regulating this expression in such cells (Bownes, 2004).

In *D. melanogaster*, *yp* genes 1 and 2 are located in close proximity in opposite orientation and share a regulatory region called the intergenic enhancer region (**Figure 15**). In females, expression of *yp1* and *yp2* occurs in fat body and follicle cells of developing egg chambers at stages 8–10 (Bownes, 2004). The 1225 bp intergenic enhancer region of these *yp* genes contains four enhancer regions: fat body enhancer (FBE), hermaphrodite response region (HRR), and two ovary enhancers (OE1 and OE2) (Logan *et al.*, 1989; Logan and Wensink,

1990; Garabedian *et al*., 1985, 1986; Abrahamsen *et al*., 1993; Lossky and Wensink, 1995). FBE drives expression of these genes in fat body, and HRR responds to the *hermaphrodite* gene that acts along with Dsx to control their sex specific expression (Li and Baker, 1998). OE1 and OE2 direct expression of these genes in follicle cells (Logan *et al*., 1989; Logan and Wensink, 1990; Lossky and Wensink, 1995). With base pairing in respect to the *yp1* start site, several binding sites for activator or repressor molecules have been mapped, and binding has been demonstrated for some of these molecules (**Figure 16**). A putative binding site for *bzip3* overlaps a weak binding site for a Dsx, *dsxC*. Two overlapping binding sites for the mammalian CAAT enhancer binding protein (C/EBP) and the adult enhancer factor-1 (AEF-1) have been found in other fat body enhancers and the *Adh* gene of the mammalian liver to activate or repress transcription, respectively (Abel *et al*., 1992). These two sites, in turn, overlap the strongest binding site for Dsx, *dsxA* (Bownes *et al*., 1996). Further upstream, between −322 and −1225 bp, up to the *yp2* transcription start site, lies the HRR, which contains the binding site for the hermaphrodite protein, and OE1. A putative EcRE lies within OE1. A second EcRE is found between −482 and −494 bp of the HRR region. OE2 is located at the start site for *yp2* transcription (Logan *et al*., 1989; Logan and Wensink, 1990; Lossky and Wensink, 1995; Bownes, ; Bownes, personal communication).

The *D. melanogaster yp3* gene is separated from two others on the X-chromosome and has a separate regulatory region, the upstream Enhancer 3 (Hutson and Bownes, 2003). The organization of the regulatory regions of this gene differs from those of *yp1* and *yp2*, resembling instead those in *Musca* and *Calliphora yp* genes (Hutson and Bownes, 2003). The 703 bp upstream enhancer sequence of the *yp3* transcription start site contains three regions that confer tissue specificity, sex specificity, and ovary specificity (**Figure 16**). The 419 bp fat body enhancer 3 (FBE3) is the furthest 5′ regulatory region spanning from −704 to −285 bp and controls expression of *yp3* in the female fat body (Hutson and Bownes, 2003). Most 5′ in the FBE3 is the binding site for *dsxA*. Downstream of the *dsxA* site is the overlapping binding site, also found in FBE1/2, for the activator molecule CAAT enhancer binding protein (C/EBP), and the repressor, adult enhancer factor 1 – AEF-1 (Falb and Maniatis, 1992a, 1992b). The region between −498 and −252 bp is essential for sex specificity. There are two binding sites for the box-B binding factor (BBF), a transcriptional activator (Abel *et al*., 1992). A possible mechanism also involves a putative homolog of the unknown activator R that has also been found to be the final determinant needed for female specific fat body expression of *yp1* and 2 (Ronaldson and Bownes, 1995; Hutson and Bownes, 2003).

Hutson and Bownes (2003) have analyzed the regulation of *yp3* gene expression. JH increased stability of *yp3* transcripts, and 20E plays an important role in regulating transcription. Three putative EcREs have been mapped in FBE3 and *yp3* (Hutson and Bownes, 2003). Immediately 3′ to the FBE3 is the ovarian enhancer 3 (OE3) that is necessary for regulation of *yp3* transcription in the follicle cells of the developing egg chamber between stages 8 and 10. Within this region is an EcRE, and a second EcRE is located 3′ of the intronic sequence of *yp3*. The final EcRE is found within the second exon of *yp3*. 20E can override the negative effects of Dsx^{M} while maintaining the tissue specificity of *yp3* gene expression (Hutson and Bownes, 2003). Experiments using upstream, downstream, and coding sequences of *yp3* fused to reporter genes agree well with the locations of the putative EcREs, because there are ecdysteroid inducible sites upstream, downstream, and in the coding region (Hutson and Bownes, 2003).

3.9.2.6. Hormones and Ovarian Maturation

3.9.2.6.1. Previtellogenic development of the follicle Several aspects of ovarian previtellogenic development in insects are controlled by JH. Stimulation of previtellogenic growth of follicles by JH is best supported by past studies (Strong, 1965; Gwardz and Spielman, 1973; Tobe and Pratt, 1975; Tobe and Stay, 1977; Lanzrein *et al*., 1978; Moobola and Cupp, 1978; Tobe and Langley, 1978; McCaffery and McCaffery, 1983). Differentiation of the follicular epithelium is another aspect of oocyte development that is regulated by JH (Davey and Hubner, 1974; Abu-Hakima and Davey, 1975; Elliot and Gillot, 1976; Koeppe and Wellman, 1980; Koeppe *et al*., 1980). In *M. domestica*, JH is released soon after adult emergence, and it is essential for ovarian maturation, since without it ovaries remain immature (Adams, 1974, 1980). JH stimulates endopolyploidy in the nurse cells, primes the oocyte for growth, and potentially plays a role in follicle morphogenesis. Although, JH affects the previtellogenic stages of *M. domestica* oogenesis, it does not induce vitellogenesis. JH also is required for oocyte development in the mosquito *A. aegypti*, where it controls growth and differentiation of the follicular epithelium. These events are blocked by the removal of CA and restored by either implantation of CA or application of JH (Raikhel and Lea, 1991).

3.9.2.6.2. The role of 20E in ovarian development and egg maturation in Diptera Ecdysteroids are produced by the ovaries of many insects, including mosquitos and flies (Hagedorn *et al*., 1975; Bownes *et al*., 1984; Hagedorn, 1985). However, their role in ovarian development is not completely understood. In *D. melanogaster*, ecdysteroids can have an antagonistic effect on oocyte progression and lead to apoptosis of egg chambers. Ecdysteroid mutants, such as *ecd*[1] (Redfern and Bownes, 1982) and *l(3)3*^{DTS} (Walker *et al*., 1987), have defects in the progress of oogenesis. One of the early genes in the ecdysteroid regulatory hierarchy, *BR-C*, is crucial at several stages of oogenesis. It is first expressed in all follicle cells surrounding the oocyte prior to the control point (Deng and Bownes, 1997), and this early *BR-C* induction may be controlled by ecdysteroids. An exciting development is the isolation of the *D. melanogaster dare* gene that encodes adrenodoxin reductase, which is expressed in the ovary and plays a key role in ecdysteroid biosynthesis (Freeman *et al*., 1999) (see **Chapter 3.3**). These authors postulated that ovarian expression of *dare* provides a maternal source of this enzyme to the developing embryo. Since it is first expressed just prior to activation of the *BR-C*, it is also possible that it could also support the synthesis of ecdysteroids, which would activate *BR-C* in nearby follicle cells at this stage of oogenesis. This scenario suggests the existence of an egg chamber autonomous timing event that regulates when and where ecdysteroids are available to control oocyte progression. *BR-C* expression in oogenesis is crucial for the regulation of endoreplication of polyploid follicle cells, specific amplification of the chorion genes, and later for positioning of the chorionic appendages (Deng and Bownes, 1997; Tzolovsky *et al*., 1999).

Although *BR-C* is regulated by ecdysteroids in early oogenesis, the epidermal growth factor signaling pathway in the egg chamber is crucial for positioning the late *BR-C* expression pattern, which in turn positions the chorionic appendages (Deng *et al*., 1999). Since the effects of 20E are mediated by EcR and USP, mutations in these genes in *D. melanogaster* affect oogenesis. EcR-A and Ec-R-B1 are expressed in the nurse cells and follicle cells throughout oogenesis (Deng, Mauchline, and Bownes, personal communication). A temperature sensitive mutant affecting these isoforms, EcR^{A483T}, reduced egg laying, induced abnormal egg clusters, and led to a loss of vitellogenic stages (Carney and Bender, 2000). Loss of EcR in germline clones leads to egg chamber arrest at around stage 6–7 of follicle development (previtellogenic stage). Carney and Bender (2000) proposed the existence of an ecdysone dependent checkpoint at this stage. Buszczak *et al*. (1999) have shown that the early ecdysone response genes, *E75* and *E74*, along with the *BR-C*, are crucial for egg chamber morphogenesis in mid-oogenesis. Germline clones of cells lacking *E75, dare*, or EcR functions results in the degeneration of these egg chambers at stage 8 (Buszczak *et al*., 1999).

3.9.2.6.3. Regulation of patency by follicle cells The appearance of large intercellular spaces in the follicular epithelium during vitellogenesis, a phenomenon termed patency, has been reported in many insects, from the less modified species having panoistic ovaries, like *B. germanica* (**Figure 17**)

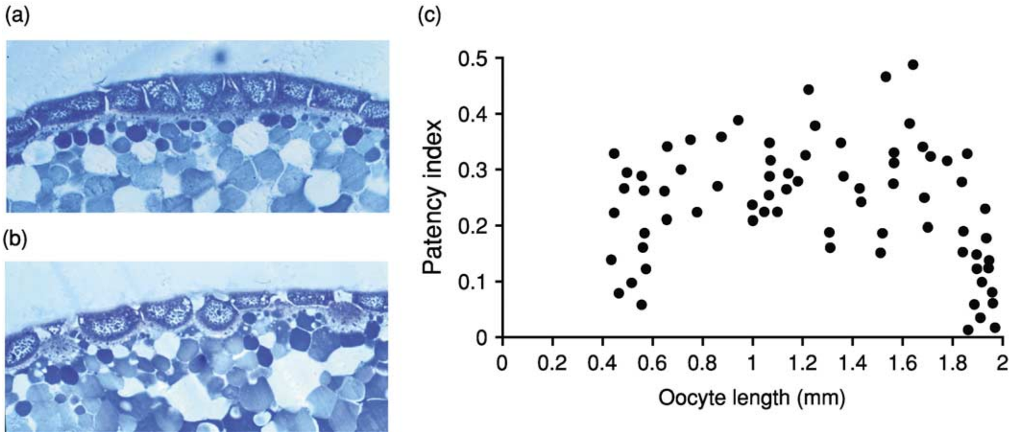

Figure 17 Patency of follicle cells in *Blattella germanica* during yolk protein uptake. (a, b) Sections at the equatorial zone in basal oocytes of (a) 0.68 mm length (3 days old) and (b) 1.52 mm length (5 days old). (c) Relation between patency index (PI) and basal oocyte length. PI = SE/SC, where SE is the surface of the intercellular spaces stained with Evans' blue, and SC the surface of the follicle cells. (Reprinted with permission from Pascual, N., Cerdà, X., Benito, B., Tomás, J., Piulachs, M.D., *et al*., **1992**. Ovarian ecdysteroid levels and basal oocyte development during maturation in the cockroach *Blattella germanica* (L.). *J. Insect Physiol. 38*, 339–348, with permission from Elsevier.)

(Pascual *et al.*, 1992) to the most modified ones having polytrophic ovaries, like flies or mosquitos (Wyatt and Davey, 1996). Studies on *Rhodnius prolixus* by Davey and co-workers have suggested that patency is under JH control (Wyatt and Davey, 1996). Further studies in this bug have shown that JH increases the activity of Na^+/K^+ ATPase in membrane preparations from vitellogenic follicle cells incubated *in vitro*, and experiments with inhibitors and activators of protein kinase C indicated that this enzyme is involved in the activation of the ATPase (Sevala and Davey, 1989). Incubation of membrane preparations with JH I resulted in the phosphorylation of a 100 kDa protein, a process that was dependent on protein kinase C and was inhibited by ouabain. Based on these experiments, it was suggested that the 100 kDa protein could be the α-subunit of the ATPase (Sevala and Davey, 1993). According to this model, JH would act on the follicle cells via a protein kinase C dependent cascade to stimulate a membrane bound Na^+/K^+ ATPase (**Figure 18**). Then, changes in the ionic balance would cause water loss and shrinkage of the cells with the associated apparition of large intercellular spaces. An equivalent system seems to operate in the locust *L. migratoria* (Davey *et al.*, 1993) and the mealworm beetle, *Tenebrio molitor* (Webb *et al.*, 1997). The model proposed to explain these mechanisms acting in follicle cell patency (**Figure 18**) suggests the existence of a membrane receptor that binds JH. The first efforts to characterize such a receptor were carried out in *R. prolixus*. In this species, Ilenchuk and Davey (1985) have shown that JH I binds to membrane preparations of follicle cells with a K_d of 6.54 nM in a specific and saturable fashion. Neither JH II nor JH III exhibited biological activity, and they did not compete for the binding site (Ilenchuk and Davey, 1987). A 35 kDa protein in solubilized follicle cell membranes from *L. migratoria* was found to bind a photoaffinity analog of JH III, [^{3}H]EFDA (Sevala *et al.*, 1995). The membrane preparations bound [^{3}H]JH III with a K_d of 3.68 nM in a specific and saturable fashion, and the binding of EFDA was blocked when membranes were previously treated with JH III. Interestingly, EBDA, a photoaffinity analog of JH I, did not show any specific binding in equivalent assays; EHDA, a photoaffinity analog of JH II, bound specifically to a 35 kDa protein, and MDK, a photoaffinity analog of methoprene, bound specifically to a different 17 kDa protein (Sevala *et al.*, 1995). Although relatively small, these JH binding proteins may serve as membrane receptors; certainly the 35 kDa protein is within the size range of G protein-coupled receptors (see **Chapter 5.5**). Further investigations are required to elucidate the nature of these proteins.

Webb and Hurd (1995) have reported specific and saturable binding of JH III to microsomal preparations of vitellogenic follicle cells from the beetle, *T. molitor.* Results of Scatchard analysis indicated the occurrence of two sites of different affinity, one with a K_d of 10 nM and the other one of 400 nM. Both sites showed modest affinity for JH I. The specificity of JH binding by follicle cell membranes from the above species is intriguing, given the structural similarity of JH homologs: *R. prolixus* to JH I only, *L. migratoria* to JH III and II, and *T. molitor* to JH III and also JH I. Coincidently, JH III is found in *L. migratoria* and *T. molitor*, while that of *R. prolixus* is unknown.

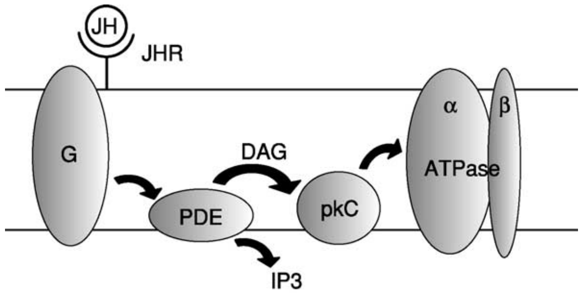

Figure 18 Model for the action of JH on the follicle cell membrane. The binding of JH to the JH receptor (JHR) on the outer surface of the membrane triggers a cascade involving a G protein, with which the receptor site is closely associated. Protein kinase C (pkC) is activated through phosphodiesterase (PDE) and diacylglycerol (DAG) and phosphorylates the α-subunit of the Na^+K^+ ATPase, thus activating the enzyme. (Modified from Wyatt, G.R., Davey K.G., **1996**. Cellular and molecular actions of juvenile hormone. II. Roles of juvenile hormone in adult insects. *Adv. Insect Physiol. 26*, 1–155.)

3.9.2.6.4. Development of oocyte endocytic complex and endocytosis When YPs reach the plasma membrane of oocytes (oolemma), they are internalized into the ooplasm through receptor mediated endocytosis, via coated pits and vesicles, and transferred to early endosomes in the cortical ooplasm. From early endosomes they are conveyed to yolk spheres, while receptors are recycled back to the oocyte surface (Raikhel and Dhadialla, 1992; Sappington and Raikhel, 1998a; Snigirevskaya and Raikhel, 2004; Raikhel *et al.*, 2002). In *D. melanogaster*, the endocytic pathway leading to the production of yolk spheres was visualized by Giorgi *et al.* (1993) with exposure to peroxidase *in vivo* or *in vitro*. The Golgi apparatus and the yolk spheres were then labeled by fixation with osmium zinc iodide (OZI). Starvation resulted in the OZI labeling being restricted to the Golgi apparatus and to an

extended tubular network, whereas feeding or treatment with JH caused the yolk spheres to become labeled with OZI and to incorporate peroxidase. Similar results were obtained in equivalent experiments with the mutant *ap⁴*, which is defective in JH biosynthesis, or with vitellogenic follicular tissue incubated *in vitro* and treated or not with JH. The results of this study indicated that JH facilitates endocytic uptake by inducing the fusion of coated vesicles and tubules with the yolk spheres (Giorgi *et al.*, 1993).

D. melanogaster ap⁴ mutant flies produce low levels of JH and ovarian ecdysteroids and are infertile (Richard *et al.*, 1998, 2001) This situation suggests that JH has a prominent role in regulating YP uptake by the ovary, given that the endocytic organelles are absent in *ap⁴* oocytes and YPs are present at normal levels in the hemolymph. The development of endocytic organelles can be restored in *ap⁴* flies by application of JH in a fashion similar to that of mosquito. In insects with continuous egg production such as *D. melanogaster*, it is not clear whether JH regulates the formation of endocytic organelles, stimulates the endocytosis itself or acts in both events, because these events are difficult to separate.

In insects with cyclic egg production, early developmental and vitellogenic events in egg chambers are separated at the arrest stage, which is broken by either food intake or other stimuli. Normally, these insects mature only a single egg per ovariole in each cycle. Raikhel and Lea (1985) have shown that during the JH dependent previtellogenic period of follicle development in the mosquito *A. aegypti*, a highly specialized endocytic complex consisting of microvilli, numerous coated vesicles, and endosomes appears in the oocyte cortex. The formation of this endocytic complex is controlled by JH III. It was blocked by CA ablation at eclosion, but restored by either CA implantation or the application of JH III. Analysis of several genes involved in receptor mediated endocytosis of YPs, e.g., clathrin heavy chain (Kokoza and Raikhel, 1997), Vg receptor (Sappington *et al.*, 1996), and ovarian lipophorin receptor (Cheon *et al.*, 2001), has revealed that their expression occurs very early in the previtellogenic development of mosquito ovaries, even before the formation of the primary follicle. Immunocytochemistry, however, shows that the Vg receptor is present as the development of the endocytic complex occurs in the oocyte cortex (Sappington *et al.*, 1995). These findings suggest that JH likely acts at the posttranscriptional level on these genes in a manner similar to that in the fat body (Zhu *et al.*, 2003a).

3.9.2.6.5. The ovary as an endocrine organ Many different cell types and tissues make up the insect ovary, and any of these cells or tissues may produce factors that affect itself (autocrine), neighboring cells (paracrine), or more distant cells (endocrine). The ovary is a primary source of ecdysteroids in female insects, as demonstrated in many different insect groups (e.g., Whiting *et al.*, 1997; Marti *et al.*, 2003), and autocrine, paracrine, and endocrine effects have been reported or ascribed to ovarian ecdysteroids in female insects (Hagedorn, 1985; Lanot *et al.*, 1989). The follicle cells surrounding the oocyte are presumed to be the specific cell source, as first demonstrated for locusts (Kappler *et al.*, 1986; 1988), although this has not been confirmed in higher orders of insects (e.g., Diptera). Ecdysteroids are sequestered by developing oocytes in all insects and are present in hemolymph to a lesser or greater degree depending on whether they are required for vitellogenesis. In general, ovarian ecdysteroidogenesis proceeds in dictyopteran females in parallel to vitellogenesis (Pascual *et al.*, 1992; Romañá *et al.*, 1995), but in female mosquitos and higher flies, this process is initiated by neurohormones (see Section 3.9.3.8.3) released in response to the ingestion of a blood or protein meal, respectively (Hagedorn *et al.*, 1975; Trabalon *et al.*, 1990).

For insects, the detailed and complete biosynthetic pathway for the conversion of cholesterol to ecdysteroids is not known, but it is believed to mimic vertebrate steroidogenesis in that precursor steroid molecules shuttle between the endoplasmic reticulum and the inner mitochondrial membrane during processing (Gilbert *et al.*, 2002; see **Chapter 3.3**). Key proteins and enzymes involved in the ovarian ecdysteroid biosynthetic process have been identified by genetic analysis of *D. melanogaster*. Females with the *ecdysoneless* conditional mutation appear to lack the ability to transport an intermediate to the inner mitochondrial membrane for further processing at the restrictive temperature (Warren *et al.*, 1996), but the protein responsible for the mutant phenotype has not yet been identified. Expression of the adrenodoxin reductase (*dare*) gene in ovaries of *D. melanogaster* females is required in the vitellogenic stage of oogenesis (Buszczak *et al.*, 1999; Freeman *et al.*, 1999). This mitochondrial enzyme mediates the transport of electrons from NADPH to adrenodoxin, which in turn donates them to the mitochondrial cytochrome P450 enzymes responsible for steroidogenesis. The *disembodied*, *shadow*, *phantom*, and *shade* genes encode cytochrome P450 enzymes involved in the final

hydroxylation steps of ecdysteroid biosynthesis (Gilbert *et al*., 2002; Warren *et al*., 2002; Petryk *et al*., 2003) (see **Chapter 3.3** for details). These hydroxylases were localized within the adult ovary, and *disembodied* was expressed at the beginning of the vitellogenic stage of oocyte maturation (Chavez *et al*., 2000). Ecdysone is the major ecdysteroid secreted by *A. aegypti* ovaries and is converted to the more active form of 20E by the ecdysone 20-monoxygenase in peripheral tissues, such as the fat body and ovaries (Hagedorn *et al*., 1975; Borovsky *et al*., 1986; Smith and Mitchell, 1986).

The ovary may be a source of JH and peptide or protein messengers. The ovaries of *A. aegypti* synthesize *in vitro* physiologically significant amounts of JH III and other JH-like compounds from radiolabeled farnesoic acid, methionine, and acetate (Borovsky *et al*., 1994). Only one other study has investigated this phenomenon in a female insect, and under similar conditions, ovaries of *D. melanogaster* failed to produce JH (Richard *et al*., 2001). For female Diptera, ovaries with mature eggs may be the source of peptide or protein factors shown to inhibit vitellogenesis directly or indirectly (see Sections 3.9.3.8.7 and 3.9.3.8.8). Unfortunately, hemolymph titers for such factors have not been profiled in these female insects during oogenesis; thus, their physiological function remains conjectural. Several different neuropeptides have been identified in neurons and neurosecretory cells associated with oviducts (see Section 3.9.2.8), and these peptides may have paracrine and endocrine effects when released at specific times during reproduction.

3.9.2.7. Hormone Action in Female Accessory Glands

3.9.2.7.1. The role of juvenile hormone in the colleterial glands Among the insect accessory sex glands and other organs associated with fertilization and oviposition, the colleterial glands of female cockroaches have been studied preferentially with regard to the endocrine basis of development and biosynthetic activity. The asymmetrical left and right colleterial glands form the ootheca, the hard egg case deposited by female cockroaches. The right gland produces an 8-glucosidase, whereas the left gland produces calcium oxalate, protocatechuic acid-8-glucoside, other 8-glucosides, a diphenol oxidase, and a group of structural proteins called oothecins. When the secretions of both glands mix, the glucosidase reacts with the 8-glucosides, and the resulting phenols are oxidized to quinones, which cross-link the oothecins through phenolic bridges (see Koeppe *et al*., 1985). This gives the typical hard consistency of the ootheca.

The first studies demonstrating the key role of CA for accessory gland development in the cockroach *L. maderae* were reported by B. Scharrer in the 1940s. Subsequent research in other cockroach species, *P. americana* and *B. germanica*, involving allatectomy and hormonal treatment, have demonstrated that JH is essential for the production of oothecins and the other molecules in the left colleterial gland (**Figure 19**). JH does not influence production of 8-glucosidase in the right colleterial gland (see Koeppe *et al*., 1985; Wyatt and Davey, 1996).

3.9.2.7.2. Oothecins – structural proteins regulated by juvenile hormone Oothecin synthesis in *P. americana* has been used as a model to investigate the effects of JH. Oothecins are composed of a 39 kDa protein, which is rich in valine and proline, and five smaller proteins (types A–E), which are rich in glycine and tyrosine. The sequence of a C type oothecin displays a number of similarities with chorion proteins of silk moths (Pau *et al*., 1987). Expression studies in *P. americana* females have shown that the first appearance of oothecin mRNAs coincides

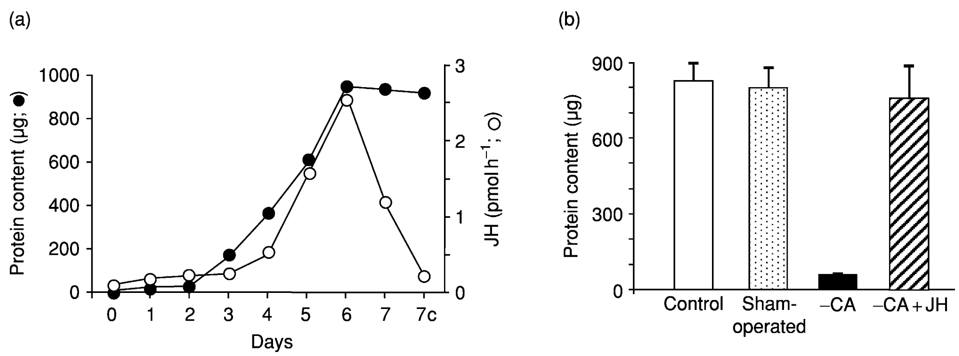

Figure 19 The increase of protein content in the female left colleterial gland of the *Blattella germanica* is paralleled by the increase in production of juvenile hormone (JH) by the corpora allata (a). Protein accumulation is regulated by JH, as shown by experiments of allatectomy (–CA) and subsequent treatment with 10 μg of JH III (–CA + JH) (b). (Based on data from Belles and Piulachs, 1983 and Danès and Piulachs, unpublished data.)

with rising rates of JH biosynthesis, whereas allatectomy abolishes their expression. No correlation was observed with the ecdysteroid concentration in the hemolymph, whereas ovariectomy, which depresses ecdysteroid titer, did not affect oothecin production (Pau *et al.*, 1987). Thus, ecdysteroids probably do not play a significant role in regulating oothecin expression. In a related study, 20E was shown to inhibit RNA synthesis *in vitro* in the left colleterial gland (Iris and Sin, 1988). This may be a pharmacological rather than physiological effect, given that the 20E dose ($1.2\,\mu g\,ml^{-1}$) was more than two orders of magnitude higher than maximal concentrations of ecdysteroids in female *P. americana* (Weaver *et al.*, 1984).

3.9.2.8. Oviposition

Oviposition by female insects is regulated by the central nervous system (CNS) in response to male accessory gland factors passed during fertilization (see **Chapter 1.5**), oocyte maturity, and physical site characteristics. Neurotransmitters and neuropeptides, acting as such, would have a direct action in activating or inhibiting this process, but JH and ecdysteroids may modulate nervous system regulation. Diverse neurotransmitters and neuropeptides have been localized in cells of the terminal ganglion that have axons extending to different oviduct regions in insects, and their effect on oviduct muscle contractions *in vitro* has been documented. Tachykinins (Kwok *et al.*, 1999), SchistoFLRFa (Kwok and Orchard, 2002), crustacean cardioactive peptide (Donini and Lange, 2002), proctolin and serotonin (Lange, 2002) stimulated such contractions, whereas octopamine and myosuppressin were inhibitory (HVFLRFa; Starratt *et al.*, 2000). The spermatheca also are innervated from the terminal ganglion, and octopamine and Arg-Phe amide peptides alter muscle contractions in these organs (Clark and Lange, 2003). Although allatostatin-A has no demonstrated effects on insect oviducts, it greatly increases in concentration in oocytes and oviduct epithelium and nerves of the female cockroach, *Diploptera punctata*, during vitellogenesis, possibly functioning as an anti-JH factor in ovaries (Woodhead *et al.*, 2003). In the cricket *A. domesticus*, ovipositor movements in a typical oviposition sequence are completely abolished in allatectomized females, whereas JH treatment restores that behavior (Strambi *et al.*, 1997). Oviposition by coleopteran females is inhibited by the application of 20E antagonists, largely due to their induction of abnormal egg maturation (hyperecdysonism) (Taïbi *et al.*, 2003).

Parturition hormone (PH) activity is present not only in the uterus of the tsetse fly *Glossina morsitans* but also in the oviducts of *Bombyx* and *Schistocerca*, as well as the ejaculatory duct of *S. gregaria* males (Zdarek *et al.*, 2000). Activity thus appears to be present in the reproductive ducts of diverse insect taxa. To determine whether any of the common insect neuropeptides are capable of mimicking the effect of PH, 35 identified neuropeptides and analogs were evaluated for PH activity. Modest PH activity was observed for only high doses of proctolin and a pyrokinin analog, thus suggesting that PH is unlikely to be closely related to any of the identified neuropeptides tested. While proctolin was highly effective in stimulating contractions of the *S. gregaria* oviduct, the extract from the tsetse fly uterus elicited only a weak response in this bioassay. PH activity, however, was effectively mimicked with an injection of 8 bromo-cyclic GMP, suggesting a potential role for this cyclic nucleotide in mediating the PH response. Neck-ligated, pregnant females were responsive to PH, other neuropeptides and cyclic nucleotides, whereas in intact females, the brain presumably negates the effects of the exogenous compounds.

3.9.2.9. Peptide Hormones Involved in Female Reproduction

As described above, JH and ecdysteroids are considered to be the primary hormones affecting female reproduction by acting separately or coordinately to stimulate oogenesis and vitellogenesis, depending on the insect group or species. Much is known about specific neuropeptides that either stimulate or inhibit JH or ecdysteroid synthesis in insects, but little evidence points to the direct effects of peptide hormones on physiological processes associated with egg maturation (reviews: Gade *et al.*, 1997; Klowden, 1997; De Loof *et al.*, 2001; Nässel, 2002; Taghert and Veenstra, 2003). In effect, neuropeptides regulating the secretion of JH and ecdysteroids could be considered the “master” hormones, because their secretion is directed by the CNS as an integrated response to external and internal cues, such as day length and nutrient stores (see **Chapter 3.2**).

Peptides acting as hormones or neurotransmitters have innumerable effects on behavior, ion and metabolite homeostasis, and locomotion, which are key to successful reproduction by insects (see **Chapter 3.10**). Only recently have comprehensive catalogs for peptide messenger genes been made available for *D. melanogaster* (Taghert and Veenstra, 2003) and *Anopheles gambiae* (Riehle *et al.*, 2002), thanks to their respective genome projects.

Approximately 40 different genes encoding peptide messengers are present in these dipterans, and many of these genes contain multiple copies of variant peptides. New peptide messenger genes await discovery in these insects, and future studies should elucidate the conservation of peptide messenger genes among insect orders. In addition, receptors for these peptides and elements of diverse signal transduction pathways have been revealed by bioinformatics in concert with gene expression and mutation for *D. melanogaster* (Taghert and Veenstra, 2003). Most importantly, elucidation of these pathways will lead to a greater understanding of how peptide messengers modulate biochemical processes and gene expression in insect cells.

3.9.2.9.1. Allatotropins The allatotropin (AT) family of structurally related peptides is so-named because the first peptide was isolated based on its stimulation of the CA *in vitro* to produce JH (see **Chapter 3.7**). In insects where vitellogenesis is JH dependent, this peptide is probably an important initiator of reproduction. The first peptide shown to have this activity was purified from head extracts of pharate adult *M. sexta* (Manse-AT; GFKNVEMMTARGFa; Kataoka *et al.*, 1989). Identical peptides and genes encoding related ones have been identified in other species of Lepidoptera (Taylor *et al.*, 1996; Oeh *et al.*, 2000; Truesdell *et al.*, 2000; Park *et al.*, 2002; Abdel-latief *et al.*, 2003). In *M. sexta*, three alternatively spliced mRNAs result from AT gene expression, which has been localized by *in situ* hybridization and immunocytochemistry to cells in the brain, frontal ganglion ventral ganglia, and midgut of different life stages (review: Elekonich and Horodyski, 2003). In *P. unipuncta*, expression of the AT gene was observed first in late pupae and continued during the adult stage (Truesdell *et al.*, 2000).

Related peptides and genes encoding such peptides have been identified in *L. migratoria* (Paemen *et al.*, 1991), a beetle (*L. decemlineata*; Spittaels *et al.*, 1996), two species of Diptera, *A. aegypti* (Veenstra and Costes, 1999) and *A. gambiae*, and in a few other invertebrates (Elekonich and Horodyski, 2003). Immunocytochemical studies with Manse-AT antisera have revealed the presence of AT-like peptides in cockroaches and two other dipterans, including *D. melanogaster* (Elekonich and Horodyski, 2003), but no ortholog AT gene has been identified in the *D. melanogaster* genome as yet (Taghert and Veenstra, 2003).

In vitro assays with adult CA are routinely used to investigate the pathway of JH biosynthesis. Manse-AT stimulates the CA to produce JH I, II, and III, but is limited by availability of farnesoic acid, a precursor (Elekonich and Horodyski, 2003). This AT also stimulates JH secretion *in vitro* by larval and adult CA of other lepidopteran species and the adult CA of the honeybee, *A. mellifera* (Rachinsky *et al.*, 2000) and blowfly, *Phormia regina* (Tu *et al.*, 2001). Similarly, JH secretion by the CA of older sugar fed female *A. aegypti* is increased *in vitro* by this species' AT or farnesoic acid alone, whereas both are required to activate JH synthesis in CA from newly eclosed females (Li *et al.*, 2003).

In adult insects, ATs have demonstrated effects on other processes associated with reproduction. *L. migratoria* AT may play a role in oviposition, as suggested by its myotropic activity on oviducts from locust and cockroach females, *Leucophaea maderae*, the basis for its isolation from male accessory glands (Paemen *et al.*, 1991). Immunocytochemistry showed that AT-immunoreactivity had a widespread and sexually dimorphic distribution in the nervous system of adult locusts and cockroaches (Nässel, 2002).

3.9.2.9.2. Allatostatins Three groups of neuropeptides in insects have been isolated based on their inhibition of JH secretion by CA *in vitro* and are known as allatostatins (ASTs). The first peptides with this bioactivity were isolated from the cockroach, *D. punctata* (Woodhead *et al.*, 1989) and are now termed the A- or cockroach-type of AST (AST-A). Typically, they are short peptides with the signature terminal sequence of F/YXFGLa, and identified AST-A cDNAs and genes encode a propeptide containing 13 or 14 peptides with slight sequence variations that are posttranscriptionally cleaved and processed (Belles *et al.*, 1999; Meyering-Vos *et al.*, 2001). The second group, known as the B- or cricket-type of AST (AST-B), is a family of peptides with a common sequence of W(X)$_6$Wa, e.g., GWQDLNGGWa and AWERFHGSWa, first identified in the cricket, *G. bimaculatus* and shown to inhibit JH biosynthesis *in vitro* in CA from virgin females (Lorenz *et al.*, 1995). Related peptides were isolated first from a locust, *L. migratoria*, based on their inhibition of oviduct contractions (Schoofs *et al.*, 1991). The third group or C-type of AST (AST-C) is represented by the 15 amino acid, non-amidated peptide (PEVRFRQCYFNPISCF), first discovered in *M. sexta* (Kramer *et al.*, 1991), based on its inhibition of JH synthesis by CA from adult moths.

All three AST types probably exist in insects, as indicated by the annotation of peptide messenger genes for *D. melanogaster* (Taghert and Veenstra, 2003) and *A. gambiae* (Riehle *et al.*, 2002), and other reports detail the isolation of related peptides

or characterization of encoding cDNAs or genes from a variety of insects (reviews: Bendena *et al.*, 1999; Stay, 2000). Numerous immunocytochemical studies have examined the distribution of AST types in a great variety of insects and even different life stages and organs (Nassel, 2002). Each AST type appears to have a unique distribution in the CNS, and the presence of an AST type in the CA is dependent on whether it affects JH secretion by the CA. Interestingly, AST-A is also present in midgut endocrine cells and hemocytes (Stay, 2000), thus suggesting an even greater endocrine repertory.

In general, it appears that one AST type inhibits JH secretion by CA in one or more life stages of a particular species, and the other types do not. The dipteran ASTs are exceptional in that none affect JH secretion by dipteran larval CA, but blowfly AST-A (callatostatin) inhibits JH biosynthesis by CA from cockroaches (Duve *et al.*, 1993). Notably, peptides from all three AST types have been shown to inhibit muscle contractions in a variety of organs from different insect groups. Receptors for ASTs have been identified in a cockroach (AST-A; Auerswald *et al.*, 2001), a silk moth (AST-A; Secher *et al.*, 2001) and *D. melanogaster*, after candidate G protein-coupled receptors (GPCR) were expressed in cell systems and shown to bind AST-A (two different GPCRs; Larsen *et al.*, 2001), AST-B (Johnson *et al.*, 2003), and AST-C (Kreienkamp *et al.*, 2002).

In addition, ASTs have demonstrated effects on female reproduction. An AST-A inhibited vitellogenin release *in vitro* by fat body of cockroach females, *B. germanica* (Marin *et al.*, 1996). The inhibitory effect was counteracted by the addition of mevalonolactone, thus suggesting that the AST-A inhibited synthesis of mevalonate, and hence dolichol, and therefore impairing the glycosylation and export of vitellogenin from the fat body. *In vitro* ecdysteroid biosynthesis by ovaries from a cricket, *G. bimaculatus*, was inhibited by an AST-B (Lorenz *et al.*, 1997), the same action as prothoracicostatic peptides in the AST-B family have on larval prothoracic glands from the silk moth, *B. mori* (Hua *et al.*, 1999; **Chapter 3.2**). Surprisingly, there are only a few reports on the *in vivo* effects of ASTs in female insects. After showing that bioactive AST-As were circulating in *D. punctata*, three synthetic AST-As were injected every 12 h for 3 days into mated females and were found to significantly decrease oocyte length and *in vitro* JH synthesis by the CA in treated females (Woodhead *et al.*, 1993). Similar injections of cricket AST-A and AST-B into female crickets, *G. bimaculatus*, resulted in decreased body and ovary weight, eggs/ovary, and ovary ecdysteroid biosynthesis and increased vitellogenin titer in hemolymph. The peptides had little or no effect on JH biosynthesis; however, these trends were not statistically significant when compared to controls (Lorenz *et al.*, 1998).

3.9.2.9.3. Ovary ecdysteroidogenic hormone and neuroparsin Ovaries in female insects produce ecdysteroids, but only in Diptera do these hormones direct the increased gene expression required for vitellogenesis. In a series of classic endocrine studies on female mosquitos, the first "egg development neurosecretory hormone" or gonadotropin was described for insects (Lea, 1972). Almost 30 years later, this hormone was isolated from the heads of female *A. aegypti*, structurally characterized as an 86 residue peptide, and renamed "ovary ecdysteroidogenic hormone" (OEH), based on its direct stimulation of ecdysteroid synthesis by ovaries *in vitro* (Brown *et al.*, 1998). Immunocytochemistry with OEH antiserum stained clusters of medial neurosecretory cells in brains, as well as other cells in the ventral ganglia and midguts of larvae and both sexes of *A. gambiae* and *A. aegypti* (Brown and Cao, 2001). Cloning of the OEH cDNA revealed the OEH prohormone and led to the bacterial expression of a recombinant OEH that was shown to have the same bioactivity *in vitro* and stimulated vitellogenesis and subsequent yolk deposition; this is considered to be an indirect effect of increased ovarian ecdysteroidogenesis (Brown *et al.*, 1998). An ortholog OEH gene has been identified in another mosquito, *A. gambiae*, but not in *D. melanogaster* (Riehle *et al.*, 2002).

In Diptera, activation of ovarian ecdysteroidogenesis by OEH or other brain factors may occur through either an insulin signaling pathway (see below) or a G protein-coupled receptor (GPCR)/cAMP pathway (Shapiro, 1983). Factors with OEH activity have been extracted from brains of higher flies (Adams and Li, 1998), and in the blowfly, *Phormia regina*, ovarian steroidogenesis is stimulated *in vitro* by cAMP analogs and preceded by a peak in ovarian cAMP levels after a protein meal (Manière *et al.*, 2000). This study also showed that crude brain extracts, as well as separate extracts of the medial neurosecretory region and the rest of the brain, stimulated ovarian ecdysteroidogenesis *in vitro* but, surprisingly, the medial neurosecretory extracts did not elicit an increase in ovarian cAMP levels, whereas the crude brain and nonneurosecretory region extracts did. These results offer additional support for the existence of ecdysteroidogenic brain factors in female flies that act through different signaling pathways.

Mosquito OEHs are closely related to the neuroparsins first isolated from the corpora cardiaca of

L. migratoria (Girardie *et al.*, 1987). Experiments showed that the purified native A and B forms (83 and 78 residues, respectively) administered to adult females inhibited oocyte growth, whereas injection of neuroparsin antibody alone had the opposite effect (Girardie *et al.*, 1987). These are considered to be anti-JH effects, since JH is required for vitellogenesis in locusts, and ecdysteroids have no known role, but the mechanism for these effects remains unknown. Neuroparsins also elevated trehalose and lipid levels in hemolymph of male locusts (Moreau *et al.*, 1988) and act as antidiuretics on rectal pads (Girardie and Fournier, 1993).

As revealed by the cloning of *L. migratoria* neuroparsin cDNA, both neuroparsin forms are processed from a prohormone (Langueux *et al.*, 1992). Other neuroparsins have been isolated and identified in the locust, *Schistocerca gregaria*, and have a similar bioactivity (Girardie *et al.*, 1998a). More recently, four different neuroparsin transcripts/cDNAs have been identified in *S. gregaria* (Janssen *et al.*, 2001; Claeys *et al.*, 2003); two of the transcripts were present only in brains of all life stages, whereas the other two transcripts were in the CNS, fat body, and male accessory glands and testis. Northern blot analyses showed that levels of all four transcripts changed throughout the life stages, with a significant increase in the two widely distributed ones preceding the sexual activity of males and females. Peptides for three of the transcripts have yet to be isolated, thus their role in reproduction is unknown.

Locust neuroparsins and mosquito OEHs constitute a peptide family, as substantiated by an analysis of nucleotide and protein sequence databases that revealed neuroparsin related peptides in the honeybee and diverse arthropod and mollusk species (Claeys *et al.*, 2003). This analysis further suggested that conserved features of these peptides are shared by insulin-like growth factor binding proteins, which modulate growth factor activity, in vertebrates.

3.9.2.9.4. Ovary maturing parsin A neurohormone was isolated from female locusts, *L. migratoria*, based on its stimulation of vitellogenesis and oocyte growth, and was thus designated "ovary maturating parsin" (OMP; Girardie *et al.*, 1991). The peptide of 65 residues occurs in two isoforms, differing only at one residue position. With immunocytochemistry, OMP was localized in brain neurosecretory cells and the corpora cardiaca of locusts in all stages (Richard *et al.*, 1994). In a later study, sets of female *L. migratoria* were injected daily with different amounts of OMP over 10 days after eclosion and found to have significantly increased hemolymph titer of ecdysteroids and oocyte length over controls (Girardie *et al.*, 1998b). OMP has been identified in another locust, *S. gregaria*, and exists as isoforms: two long forms corresponding to those of *L. migratoria* OMP and two shorter forms found only in mature adults (Girardie *et al.*, 1998b). Injection of mixed OMPs in female *S. gregaria* over 12 days similarly affected ecdysteroid and vitellogenin levels in hemolymph and stimulated oocyte growth, relative to controls (Girardie *et al.*, 1998b). Although locust OMPs are considered ecdysteroidogenic and gonadotrophic peptides *in vivo*, no direct effects have been reported for OMP on isolated locust ovaries or fat body, thus, the mode of action needs further study. OMPs are known to exist in acridian Orthoptera, but not in other insects (Richard *et al.*, 1994), as indicated by the failure to identify related peptides in the *D. melanogaster* and *A. gambiae* genome databases.

3.9.2.9.5. Short neuropeptide F, neuropeptide F, and head peptides The sequences of a great diversity of insect neuropeptides end in Arg-Phe-NH_2, and three such peptides of relevance were isolated from the Colorado potato beetle, *L. decemlineata*, (ARGPQLRLRFa and APSLRLRFa; Cerstiaens *et al.*, 1999) and the locust, *S. gregaria* (YSQVARPRFa; Schoofs *et al.*, 2001). In a subsequent experiment, multiple injections of the beetle peptides into virgin female locusts, *L. migratoria*, significantly increased oocyte growth relative to controls (Cerstiaens *et al.*, 1999). Injection of the *S. gregaria* peptide stimulated ovarian growth in female *S. gregaria*, presumably due to the increased vitellogenin levels in the peptide treated females (Schoofs *et al.*, 2001). It has not been determined whether these effects are specific to vitellogenesis or protein synthesis in general.

The two beetle peptides, along with peptides identified in other insect and arthropod species, belong to a "short neuropeptide F" (sNPF) family, as clearly indicated by ortholog genes in *D. melanogaster* (Taghert and Veenstra, 2003) and *A. gambiae* (Riehle *et al.*, 2002) that encode related short peptides ending in RLRFa or RLRWa. A functional GPCR for the *D. melanogaster* sNPFs has been characterized and its tissue expression characterized (Mertens *et al.*, 2002; Feng *et al.*, 2003), but no other bioactivities are known for insect sNPFs. The "head peptides" first identified in *A. aegypti* and later shown to inhibit host seeking behavior in nonoogenic females (Brown *et al.*, 1994) are not members of the sNPF family, as indicated by their terminus, KTRFa, and the structure of the *Aedes* head peptide cDNA (Stracker *et al.*, 2002).

Surprisingly, analysis of the *D. melanogaster* and *A. gambiae* genome databases revealed no ortholog "head peptide" genes (Riehle *et al*., 2002).

The sequence of the *S. gregaria* peptide (probably a fragment) is more similar to the C-terminus of longer peptides (36 residues almost invariably) in the "neuropeptide F/Y" family of invertebrate and vertebrate peptides (Stanek *et al*., 2002). A functional GPCR for the *D. melanogaster* NPF has been characterized (Garczynski *et al*., 2002), and in *D. melanogaster*, NPF controls foraging and social behavior by larvae (Wu *et al*., 2003), but no bioactivities are known for adults.

3.9.2.9.6. Insulin-like peptides and the insulin signaling pathway Insulin-like peptides (ILPs) are known for only a few insect species: *L. migratoria*, three species of Lepidoptera, and *D. melanogaster* (review: Claeys *et al*., 2002). In all but the locust, multiple ILP genes have been identified, with *B. mori* having an astonishing 32 ILP genes (also known as "bombyxins") and *D. melanogaster* and *A. gambiae*, each with 7 ILP genes (Krieger *et al*., 2004). In insects, clusters of neurosecretory cells in the medial, dorsal region of brains are immunostained by insulin and ILP antisera in different life stages and species (Cao and Brown, 2001; Rulifson *et al*., 2002). The gut and reproductive tract may be another source of ILPs as reported for a few insect species (Montuenga *et al*., 1989; Iwami *et al*., 1996); these organs are the primary sources of insulin and related peptides in vertebrates. The presence of ILPs in hemolymph of larvae and adult silk moths has been established, and the ILP titer is much higher in males after eclosion (Satake *et al*., 1999).

As characterized for vertebrates and invertebrates, insulin and related peptides act primarily through a receptor tyrosine kinase and an insulin receptor substrate (IRS), phosphatidylinositol 3-kinase (PI3K)/protein kinase B/Akt signaling pathway (Oldham and Hafen, 2003). For insects, the expression and function of proteins comprising this pathway have been characterized in detail only for *D. melanogaster* (Garofalo, 2002), and ortholog genes of the proteins were identified in *A. gambiae* (Riehle *et al*., 2002). An ever-increasing number of studies show that this pathway is a nexus for the transcriptional and translational regulation of growth and longevity in *D. melanogaster* and other animals (Oldham and Hafen, 2003; Tatar *et al*., 2003).

Perturbations in any gene encoding ILPs or proteins in this pathway result in multiple and dramatic effects on not only embryonic and postembryonic development, but also oogenesis and vitellogenesis in female *D. melanogaster*. Females with an ILP gene mutation had at most a single vitellogenic oocyte in each ovariole and thus a much reduced fecundity, in comparison to wild-type females (Ikeya *et al*., 2002). Mutations in the gene encoding the insulin receptor (IR) result in sterile females due to reduced ovariole development and yolk deposition (Chen *et al*., 1996). Females with an IR mutation are longer lived but deficient in JH synthesis by the CA and ovarian ecdysteroid production (Tatar *et al*., 2001; Tu *et al*., 2002). Treatment of these mutant flies with a JH analog initiates vitellogenesis and restores normal life expectancy. Vitellogenesis is blocked in females with a homozygous mutation in the IRS gene (Drummond-Barbosa and Spradling, 2001), yet another step in this key pathway.

There are only a few studies of the insulin signaling pathway in other insects. In the mosquito *A. aegypti*, the expression pattern and phosphorylation states of the IR and PKB/Akt in ovaries were characterized through previtellogenic arrest and a gonotrophic cycle after a blood meal (Riehle and Brown, 2002, 2003). Bovine insulin stimulates ecdysteroidogenesis by *A. aegypti* ovaries directly in a dose-dependent manner *in vitro*, whereas specific inhibitors of tyrosine kinase activity and PI3K inhibit ecdysteroid production (Riehle and Brown, 1999). In Lepidoptera, a putative IR was identified in tissues from *M. sexta* larvae with an IR antiserum (Smith *et al*., 1997), and ovarian cells from three species showed high-affinity binding to a silk moth ILP, presumably to ovarian IRs recognized by an IR antiserum (Fullbright *et al*., 1997).

Recently, the panoply of insulin-like peptide regulation in *D. melanogaster*, in part, has been shown to act through forkhead transcription factors and is nutrition dependent (Junger *et al*., 2003). The possibility also exists that insect ILPs may activate MAP kinases and G protein-coupled receptor/cAMP pathways (see **Chapter 3.2**), as shown for insulin related peptides in vertebrates (Hsu *et al*., 2002; Oldham and Hafen, 2003), and even elicit cross-talk between signaling pathways. Conceptually, this activation of multiple pathways by ILPs has the potential to exhibit as profound an effect on the expression of genes required for reproduction in insects, as do JH and ecdysteroids.

3.9.2.9.7. Ovary peptides that block vitellogenesis Unrelated peptides have been isolated from mature ovaries of dipteran species based on their ability to block egg maturation. The first such peptide (YDPAPPPPPP) was extracted from the ovaries of the mosquito, *A. aegypti*, and shown to inhibit yolk deposition in blood-fed females (Borovsky,

2003). Later, the direct action of this peptide was determined to be inhibition of proteolytic enzyme biosynthesis (see **Chapter 4.7**) in the midgut (see **Chapter 4.5**), and thus is known as a "trypsin modulating oostatic factor" (TMOF). With a TMOF antiserum, this peptide was localized to the follicular epithelium surrounding oocytes only after 24 h PBM and was not present in other tissues (Borovsky *et al*., 1994). This localization is supported by the characterization of a gene encoding a vitelline membrane protein, which contains TMOF sequences (Lin *et al*., 1993), and this protein is secreted by follicular epithelium cells.

A different peptide (NPTNLH) with this same activity was purified from ovarian extracts of the flesh fly *Neobellieria bullata* (Bylemans *et al*., 1994; Borovsky *et al*., 1996). Injection of the hexapeptide inhibited trypsin synthesis by the midgut of liver-fed flesh fly females, resulting in a reduction of circulating vitellogenin and oocyte growth. Immunoassays determined that *N. bullata* TMOF-staining was localized exclusively over yolk granules in oocytes and that a 75 kDa precursor protein was present in ovary extracts (Bylemans *et al*., 1996). A more recent study has shown that this peptide is probably a substrate for an angiotensin converting enzyme circulating in the hemolymph of female flies, and feeding of an inhibitor of this enzyme enhanced hemolymph vitellogenin levels (Vandingenen *et al*., 2001). A second peptide (SIVPLGLPVPIGPIVVGPR) with a similar effect was also purified from ovarian extracts of this fly (Bylemans *et al*., 1995) and named "colloostatin," given its sequence similarity to collagen. When administered *in vivo*, the peptide inhibits yolk uptake by previtellogenic oocytes and reduces the levels of circulating vitellogenin, but it does not inhibit trypsin biosynthesis in the gut.

3.9.2.9.8. Termination of vitellogenesis A few studies have shown that peptide hormones are involved in the transition from vitellogenesis to chorionogenesis so that egg maturation and ultimately oviposition can occur. Oostatic factors originating from ovaries are known for insects, and these factors may play a role in this transition through distinctly different actions, including inhibition of ovary ecdysteroidogenesis (Kelly *et al*., 1986; Adams and Li, 1998), than that reported for TMOF and other such "oostatic" factors. In dipteran females, termination of ovary ecdysteroidogenesis indirectly may end vitellogenesis, and recent studies indicate that ovarian steroidogenesis is inhibited through signaling pathways that use Ca^{2+} or cGMP as intermediates. *In vitro* ecdysteroidogenesis by vitellogenic ovaries from the blowfly, *P. regina*, was inhibited by Ca^{2+} ionophores or thapsigargin, whereas inhibitors of Ca^{2+}-calmodulin phosphodiesterases increased ecdysteroidogenesis (Manière *et al*., 2002). Analogs of cGMP inhibited *in vitro* steroid biosynthesis in vitellogenic ovaries from *P. regina*, thus correlating with the peak levels of cGMP detected in ovaries at the termination of vitellogenesis (Manière *et al*., 2003). Notably, paracrine or autocrine factors, such as nitric oxide, were implicated in this inhibition, and not brain factors, thus pointing to an even greater degree of complexity in the regulation of insect reproduction.

Th adipokinetic hormone (AKH) family has key roles in regulating lipid and carbohydrate metabolism in all life stages of diverse insects (see **Chapter 3.10**). These peptides also are known to inhibit protein and vitellogenin synthesis and RNA synthesis in female fat body and circulate in the hemolymph of ovipositing locust females (Moshitzky and Appelbaum, 1990; Glinka *et al*., 1995; Kodrik and Goldsworthy, 1995). AKH regulation occurs through a GPCR, now identified in *D. melanogaster* and *B. mori* (Staubli *et al*., 2002), and a signaling pathway with cAMP and Ca^{2+} intermediates (Gäde *et al*., 1997).

A GPCR/cAMP signaling pathway is involved in the termination of vitellogenesis in mosquitos (Dittmer *et al*., 2003). Characterization of the gene encoding a cAMP response-element binding protein in the mosquito, *A. aegypti* (AaCREB) revealed signature domains for this family of transcription factors, and this gene was constitutively expressed in female fat body, where YPs are synthesized. Elicitors of the cAMP signal transduction pathway attenuated ecdysteroid stimulated YP gene expression by fat body *in vitro*. In cell transfection assays, AaCREB served as a potent repressor of transcription, and analysis of electrophoretic mobility shift assays detected CREB specific band-shift complexes in nuclear extracts from vitellogenic fat bodies at 24 h and 36 h post-blood meal, when YP gene expression reaches its peak then terminates. Examination of the regulatory regions of Vg and vitellogenic carboxypeptidase revealed putative CREB response elements, which bound *in vitro* expressed AaCREB and offers further support for its termination of YP gene expression in the fat body of this mosquito.

3.9.3. Hormones and Male Reproduction

3.9.3.1. Spermatogenesis

Insect spermatogenesis can be divided into three main steps: (1) mitotic proliferation of spermatogonia, leading to spermatocytes; (2) meiosis of

spermatocytes, giving the spermiocytes; and (3) spermiogenesis of spermiocytes, leading to spermatozoa. As for female reproduction, ecdysteroids, JHs, and peptides have demonstrated effects on male reproductive processes.

3.9.3.1.1. Ecdysteroids and early spermatogenesis In the early steps of spermatogenesis, involving mitoses and meioses, the stimulatory role of ecdysteroids has been demonstrated in many species of Orthoptera, Hemiptera, Lepidoptera, and Diptera (Hagedorn, 1985). In *R. prolixus*, for example, mitotic division of spermatogonia takes place in the last larval instar in the absence of JH and in the presence of high levels of ecdysteroids. In addition, it has been shown experimentally that 20E increases the rate of mitosis in the spermatogonial cells (Dumser, 1980). Further corroboration of the importance of ecdysteroids in early spermatogenesis has been provided by Jacob (1992) who reported that fragments of testes from the rhinoceros beetle, *Oryctes rhinoceros*, incubated *in vitro* require ecdysteroids and the testis sheath to complete the mitotic and meiotic processes.

The stimulatory function of ecdysteroids in early stages of spermatogenesis gives physiological sense to the discovery of ecdysteroid production in the testes of the lepidopteran *Heliothis virescens* (Loeb *et al*., 1982). These authors observed that the testis sheath of tobacco budworm larvae, when incubated *in vitro*, secreted ecdysteroids into the culture medium. Testes ecdysteroid production has been demonstrated for other Lepidoptera belonging to the genera *Lymantria*, *Ostrinia*, *Mamestra*, *Leucania*, and *Spodoptera* (see Loeb *et al*., 2001 and references therein).

3.9.3.1.2. The role of juvenile hormone The role of JH in spermatogenesis is less clear. Early reports suggested that JHs antagonize the stimulatory effects of ecdysteroids, especially in early stages of spermatogenesis (see Dumser, 1980; Koeppe *et al*., 1985; Wyatt and Davey, 1996). However, other contributions have shown that JH seems to have a stimulatory effect on late spermatogenesis, especially in diapausing species when JH simultaneously accelerates spermiogenesis and interrupts the diapause (Koeppe *et al*., 1985). For example, administration of a JHA to diapausing adult leafhoppers, *Draeculacephala crassicornis*, did not influence mitosis of spermatogonia but promoted the formation of spermatozoa (Reissig and Kamm, 1974). Results obtained in the beetle, *Oryctes rhinoceros*, in addition to showing that ecdysteroids are necessary in early spermatogenesis (see above), also demonstrated that spermiogenesis took place *in vitro* only if an active CA pair was present in the incubation medium (Jacob, 1992). The stimulatory role of JH on spermiogenesis may be related to polyamine synthesis, especially putrescine, spermidine, and spermine, given that JH promotes the production of these compounds, at least in fat body and neural tissue of crickets (Cayre *et al*., 1995).

Another effect of JH related to sperm physiology has been discovered by Dean and Meola (1997) in the cat flea, *Ctenocephalides felis*. These authors have shown that sperm transfer into the epididymis is stimulated when the fleas are exposed to a filter paper treated with JH III or JHAs. As the concentration of the JHA or the exposure time increases, the percentage of fleas that transfer sperm also increases.

3.9.3.1.3. Peptides and proteins involved in spermatogenesis In relation to ecdysteroid biosynthesis in the testes, Wagner *et al*. (1997) have identified a 21 amino acid peptide (ISDFDEYEPLNDADNNEVLDF) in brain extracts of the gypsy moth, *L. dispar*, that has ecdysteroidogenic properties. Given that the peptide induces the synthesis of ecdysteroids specifically in the testes (induction experiments using prothoracic glands were unsuccessful), it has been called "testes ecdysiotropin."

Other peptide or protein factors are postulated to be directly involved in the regulation of spermatogenesis. As early as 1953, C. Williams reported the occurrence of a macromolecular factor in the hemolymph of *Hyalophora cecropia* that stimulated spermatogenesis in spermatocysts incubated *in vitro*. In 1971, Kambysellis and Williams showed that 20E allowed the entry of this factor into the testis (see Hagedorn, 1985), but since then, no such factor has been isolated. More recently, spermatid differentiation in *Drosophila* was shown to require a peptidyl peptidase ortholog of the mammalian angiotensin converting enzyme (ACE) (Hurst *et al*., 2003), and ACE mRNA is found mainly in large primary spermatocytes, whereas it is not detectable in cyst cells.

3.9.3.2. Male Accessory Gland Function

The male accessory glands of insects generally are of mesodermal origin and exhibit a wide morphological diversity, from single pairs of histologically and morphologically identical tubules to multi-paired heterogeneous tubules, with multiple forms and contents (Happ, 1992). Development of male accessory glands is regulated by ecdysteroids (review: Happ, 1992), as with many other developmental processes. This section will focus on the endocrine regulation of the biosynthetic and secretory activity of the

glands. The secretions produced by male accessory glands have a wide diversity of functions (see **Chapter 1.5**), and some of these secretions, when transferred to the female through copulation, may affect the process of vitellogenesis, as described below.

3.9.3.2.1. Products of the male accessory glands The male accessory glands synthesize and secrete a complex mixture of proteins, carbohydrates, lipids, and amino acids (Chen, 1984; see **Chapter 1.5**) that are transferred to the female during copulation. The primary function of the accessory gland products is to facilitate sperm transfer to the female. For example, these glands produce the structural proteins needed for spermatophore formation, and these spermatophore proteins may serve as nutrient resources for the female. In addition, many secretory products of the accessory glands cause physiological and behavioral changes in the mated female. These changes may be sperm related (sperm protection, storage and activation, competition with the sperm of previous males) or may alter the behavior and reproductive physiology of the mated female. The most prominent behavioral effects are the reduction of attractiveness to males and induction of refractoriness. The effects on reproductive physiology include enhancement of oocyte growth and induction of ovulation and oviposition (Chen, 1984; Gillott, 2003).

In recent years, research has been focused on Drosophilid dipterans, and more than 75 accessory gland proteins have been molecularly characterized in *D. melanogaster* (Swanson *et al*., 2001; **Chapter 1.5**). Of these proteins, the so-called sex peptide has been the most thoroughly studied compound (see **Chapter 1.5**). The sex peptide of *D. melanogaster* is synthesized as a 55 amino acid precursor, and the processed peptide depresses sexual receptivity and enhances oviposition. Ortholog peptides have been identified in other *Drosophila* species (Chen, 1996; Wolfner, 1997). In *D. melanogaster*, sex peptide stimulates the biosynthesis of JH *in vitro* by the CA of the adult female (Moshitzky *et al*., 1996). This activity is possibly related to the results of Soller *et al*. (1999), which showed that the same peptide stimulates vitellogenic oocyte progression in *D. melanogaster* and that a JHA mimics such an effect. Interestingly, the sex peptide of *D. melanogaster* stimulates JH synthesis in *Helicoverpa armigera* (Fan *et al*., 1999), which suggests that this Noctuid moth may have ortholog peptides with these allatotropic properties. Male accessory glands are an important source of JHs and related metabolites (see Section 3.9.3.2.2). These JHs can be transferred to females through copulation and enhance oocyte growth, as shown for certain lepidopterans in which JH regulates vitellogenesis (Shirk *et al*., 1980; Park *et al*., 1998).

3.9.3.2.2. Regulation of male accessory gland function by juvenile hormone In the 1940s, Wigglesworth carried out the first studies showing the importance of CA in male accessory gland function for *Rhodnius*. In the cockroach, *B. germanica*, JH influences the growth not only of the accessory glands (Piulachs *et al*., 1992) (**Figure 20**) but also of the conglobate gland (Vilaplana *et al*., 1996). Further research on other insect species, mainly orthopterans, dictyopterans, lepidopterans, and dipterans, has demonstrated that allatectomy depresses to a greater or lesser degree the accumulation of gland secretions, whereas JH treatment restores the usual secretion levels (Gillott, 1996; Wyatt and Davey, 1996). In a number of species, it has been reported that the pattern of secretion accumulation in the accessory glands is parallel to that of JH concentration in the hemolymph or to that of JH synthetic rates by the CA (Wyatt and Davey, 1996). Incubation of the male accessory glands from *D. melanogaster* with nanomolar concentrations of JH induced a nearly threefold stimulation of protein synthesis (Yamamoto *et al*., 1988). Since many accessory gland proteins in *D. melanogaster* have been characterized at the molecular level (see above and **Chapter 1.5**), monitoring expression of these genes in response to JH has become easier. For example, Cho *et al*. (2000) have shown that the protein Mst57Dc is highly expressed after eclosion, when the titer of JH III peaks, and that in the JH deficient mutant *ap56f*, the levels of Mst57Dc mRNA are about 60% of those of the wild-type.

Subsequent studies have monitored the effect of JH on the pattern of proteins, or even on particular proteins, present in accessory glands for species of Hemiptera, Orthoptera, and Dictyoptera (Wyatt and Davey, 1996). For example, allatectomy differentially affects the accumulation of various proteins present in the glands, whereas treatment with JH affects the protein pattern in the grasshopper, *Melanoplus sanguinipes* (Gillott, 1996), and in *B. germanica* (Belles and Piulachs, 1992). In *M. sanguinipes*, treatment with JH III induces the accumulation of most proteins but depresses the accumulation of two (Gillott, 1996). A later study of *M. sanguinipes* showed that JH acts directly on the accessory glands to promote synthesis of a specific protein, LHPI, which constitutes more than 50% of the protein content (Gillott and Gaines, 1992). Juvenile hormone could not stimulate LHPI synthesis in glands from allatectomized males, unless there was an

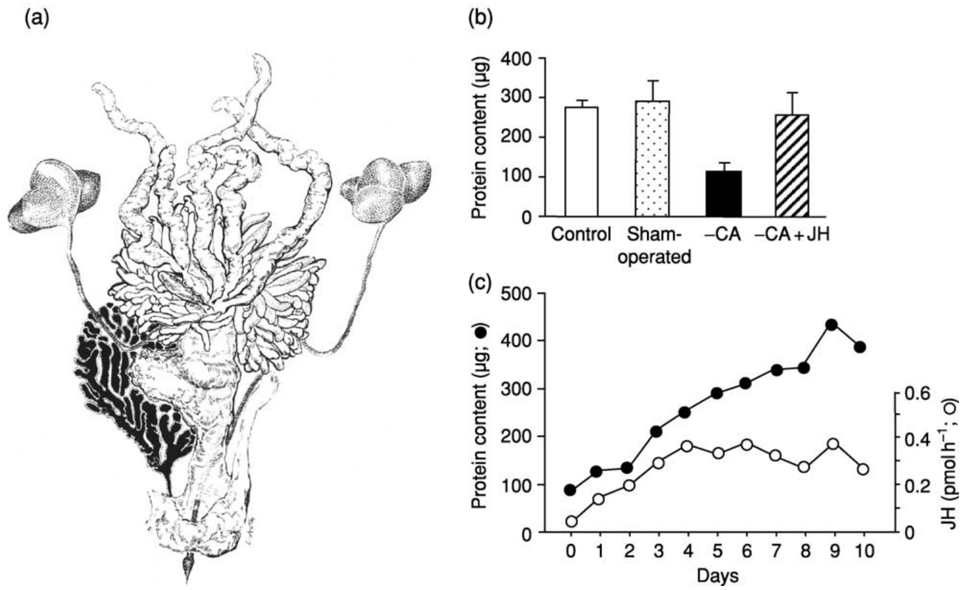

Figure 20 Protein accumulation in the male accessory glands of *Blattella germanica* (a) is regulated by juvenile hormone (JH), as shown by allatectomy experiments (−CA) and subsequent treatment with 10 μg of JH III (−CA + JH) (b). In addition, the patterns of increase in protein contents in the first days of adult life, and that of JH production by the corpora allata incubated *in vitro* are approximately parallel (c). (Based on data from Piulachs, M.D., Maestro, J.L., Belles, X., **1992**. Juvenile hormone production and accessory reproductive gland development during sexual maturation of male *Blattella germanica* (L.) Dictyoptera, Blattellidae). *Comp. Biochem. Physiol. 102A*, 477–480; and Belles and Piulachs, unpublished data.

overnight exposure to the hormone. Cycloheximide temporally abolishes the stimulatory effect of JH on LHPI synthesis in the glands of male *M. sanguinipes* (Ismail *et al.*, 1995), thus suggesting that the action of JH is mediated by protein factors involved in the transcription of LHPI. A similar priming effect of JH on protein synthesis in the accessory glands of male *L. migratoria* has been reported (Braun and Wyatt, 1995). It is worth noting that the protein Met of *D. melanogaster*, which may be involved in the action of JH action, is localized in the accessory glands and ejaculatory duct cells of adult males (Pursley *et al.*, 2000).

3.9.3.2.3. Production of juvenile hormone by the accessory glands As mentioned above, JH is a product of the accessory gland. In fact, the first active extracts of JH were obtained by Williams in the 1950s from the abdomen of the adult male of the moth, *Hyalophora cecropia*, and these glands are still known to be the most copious, natural source. It was later shown that the CA of the cecropia moth produce the acids of JH I and II and that these are converted into the corresponding JHs by the male accessory glands (Shirk *et al.*, 1983). Production of JH in the accessory glands has been reported in males of *Heliothis* as well (Park *et al.*, 1998).

JH production by male accessory glands may enable transfer of JH to females during copulation to directly enhance vitellogenesis and oocyte growth or indirectly to stimulate the female's CA. As shown for *H. virescens*, mating has an allatotropic effect, and JH measurements in males and females before and after copulation suggest the transfer of JH to females by the male (Park *et al.*, 1998). Also, production or sequestration of JH by male accessory glands may be another mechanism to regulate JH hemolymph titer or biosynthesis by CA.

3.9.3.2.4. Other hormones regulating male accessory glands Hormones other than JH also may regulate the biosynthetic activity of male accessory glands. In *R. prolixus* males, removal of certain brain neurosecretory cells impairs protein accumulation in the accessory glands, whereas treatment with JH I only partially restores protein accumulation; a peptide extracted from *R. prolixus* brains stimulates protein synthesis by isolated accessory glands (Wyatt and Davey, 1996). As these results indicate, a neuropeptide and JH are required for accessory gland function. Cerebral neurosecretion and JH are involved in male accessory gland secretory activity in another blood-sucking bug, *Panstrongylus megistus* (Regis *et al.*, 1987). In *M. sanguinipes*, cardioallatectomy inhibits the accumulation of protein LHPI to a greater degree than that provoked by allatectomy alone (Cheeseman and Gillott, 1988), which suggests again the

participation of a neurosecretory factor in the regulation of protein secretion by the male accessory glands.

Finally, 20E appears to stimulate total protein synthesis in the male accessory glands of the male lepidopterans, *S. littoralis* and *Chilo partellus* (Gillott, 1996). More detailed studies of *M. sanguinipes* have shown that 20E promotes protein accumulation in the accessory glands incubated *in vitro* (Ismail and Gillott, 1995) and that these glands incubated *in vitro* are able to produce ecdysteroids (Gillott and Ismail, 1995).

3.9.4. Future Directions

Our understanding of how JH, ecdysteroids, and peptide hormones control various aspects of insect reproduction has advanced but also broadened greatly over the last two decades. Of particular importance is the elucidation of genetic expression heirarchies regulating ecdysteroid action at the cellular level and hormonal networks controlling reproduction at the organismal level. Despite the fact that the vitellogenic action of JH is one of the hallmarks of reproduction in most insects, its precise mechanism of action remains poorly understood. Elucidating this mechanism represents the most challenging task for future research. Genetic ecdysteroid networks governing insect development and metamorphosis have been studied in detail. Our understanding of similar networks occurring in reproduction is still limited. Future studies should take advantage of techniques for gene knockout and functional genomics to gain further insight into the regulation of female and male reproduction. Likewise, these techniques offer many advantages for research on peptide hormones involved in insect reproduction.

Acknowledgments

We are grateful to Professor Mary Bownes for her kind permission to use unpublished results. We thank Dr Guoqiang Sun for his help with the manuscript, Mr. Ray E. Hardesty for editing the manuscript, Mr. Geoffrey Attardo for his help in producing figures, and Ms. Sue Gerdes for secretarial assistance.

3.10 Hormones Controlling Homeostasis in Insects

D A Schooley, University of Nevada, Reno, NV, USA
F M Horodyski, Ohio University, Athens, OH, USA
G M Coast, Birkbeck College, London, UK

3.10.1. Introduction

Insects, like other animals, face a variety of challenges to their survival in the varying conditions of their environment and food availability. Many changes in their physiological status must be controlled to achieve homeostasis. In this chapter the hormonal controllers of the supply of endogenous metabolic energy, as well as the hormonal control of fluid and electrolyte balance are discussed. A review on the same subject has appeared recently, but is significantly less detailed (Gäde, 2004).

Due to the wide variety of environmental niches inhabited by insects, the mechanisms for control of homeostasis may show considerable variation between genera, although basic underlying themes are conserved. Insects are an extremely ancient grouping of organisms, with short lifespans and frequently multiple generations per year. On completion of sequencing of the *Anopheles gambiae* genome, the genome and proteome of this dipteran insect were compared with that of the related dipteran *Drosophila melanogaster* (Zdobnov *et al*., 2002). One of the salient conclusions is that these two "closely related" dipterans show greater genetic divergence than do the genomes of the human and the pufferfish, although the estimated time of divergence between these two dipterans (~250 million years ago) is considerably more recent than that between the higher organisms (Zdobnov *et al*., 2002). This rapid rate of evolution is reflected in differences in the nature of main substrates used as metabolic fuels for flight, in considerable interspecific diversity in structure between hormones in certain families that regulate homeostasis, especially diuretic hormones, and also in differences in which family of diuretic hormones appears to dominate as the major controllers of fluid excretion between different genera. It has also become apparent that signal transduction pathways for a given family of homeostatic hormones may differ between genera.

It is interesting to compare and contrast the depth of our current knowledge in this area to that when the first edition of this series was published. At that time, the sequences of only two insect neuropeptides were known: proctolin and adipokinetic hormone (AKH) from *Locusta migratoria* (herein called Locmi-AKH-I). Technical advances in peptide isolation and analysis made in the early 1980s were responsible for an explosive growth in the isolation and identification of new insect neuropeptides. The

availability of synthetic peptide hormones then allowed detailed studies of their mechanism of physiological action. It has also become clear, as will be seen in this chapter, that insect peptide hormones, like their vertebrate homologs, frequently have more than one function. Well over 100 insect neuropeptides have been identified, belonging to a number of families. The majority of these were isolated on the basis of their myotropic activity, because of the ease and rapidity of bioassays for such effects. Owing to a huge literature, only those myotropic peptides are covered (certain forms of AKH and the myokinins) that are known to be important homeostatic regulators.

3.10.2. Hormonal Control of Energy Stores

It is difficult to discuss this section without considering comparative endocrinology. In vertebrates the storage of fats in adipose tissue and storage of glycogen in muscles and liver are increased by high levels of insulin. Mobilization of fats from adipocytes and glycogen from liver and muscles is triggered by high levels of the counter-regulatory hormone glucagon. Glucagon acts through the cyclic AMP signal transduction pathway to activate hormone sensitive lipase in adipocytes, to activate glycogen phosphorylase and inactivate glycogen synthase in muscle and liver, and to activate gluconeogenesis and inactivate glycolysis in liver and kidney. Insulin, by activating cAMP phosphodiesterase and phosphoprotein phosphatase I, has the opposite effects on these pathways.

In insects the adipokinetic-hypertrehalosemic hormones have the same role as glucagon in animals. However, a great deal of research has failed to reveal a hormone with a counter-regulatory action, although a very recent discovery by Clynen *et al.* (2003a) may shed light on this area.

3.10.2.1. Adipokinetic Hormone and Hypertrehalosemic Hormone

3.10.2.1.1. Biological role of AKH Peptides in the AKH family stimulate metabolism by mobilizing energy stores in the fat body. The actions mediated by the AKH peptides are critical to supply energy to tissues, such as the flight muscles, with substrates necessary to maintain long distance flight. Depending on the insect species, either lipids, carbohydrates, proline, or a combination thereof, are released from the fat body during times of metabolic need. For example, the energy substrate released into the hemolymph of cockroaches is trehalose, a disaccharide of glucose and the major hemolymph carbohydrate of insects (Friedman, 1985). When energy demands are high, locusts release predominantly diacylglycerols from the fat body, which are transported by lipophorins in the hemolymph (Chino and Gilbert, 1964, 1965; Soulages and Wells, 1994) (see **Chapter 4.6**), but also release carbohydrate under some conditions (Goldsworthy, 1969). Proline is released into the hemolymph to provide fuel for the contraction of flight muscles in the tsetse fly (*Glossina morsitans*; Bursell, 1963) and in coleopteran insects (De Kort *et al.*, 1973; Gäde and Auerswald, 2002). Peptides that primarily mobilize lipids in the species in which they were isolated are referred to as AKH (Mayer and Candy, 1969a), while peptides whose predominant role is to mobilize carbohydrates are known as hypertrehalosemic hormones (HrTH), since the increase in total carbohydrate is accounted for by an increase in trehalose. The adipokinetic and hypertrehalosemic functions of AKH peptides are similar to the metabolic responses induced by the vertebrate hormone, glucagon.

AKH peptides are synthesized by, and released from, the cells of the glandular lobe of the corpus cardiacum (CC) (Goldsworthy *et al.*, 1972a), an endocrine organ attached to the brain. The effect of the CC on metabolism was first described in *Periplaneta americana*, where injection of a CC extract into adult cockroaches caused an increased level of trehalose in the hemolymph and a decrease in fat body glycogen content (Steele, 1961). In the locusts *Schistocerca gregaria* and *L. migratoria*, injection of a CC extract into the hemolymph increases levels of diacylglycerol (Beenakkers, 1969; Mayer and Candy, 1969a), resembling the changes in lipid composition that occur during flight (Beenakkers, 1965; Mayer and Candy, 1967). This elevation of diacylglycerol reflects the oxidation of lipids as the primary fuel during prolonged flight in locusts (Weis-Fogh, 1952). The onset of flight is rapidly followed by the release of AKH into the hemolymph to mobilize energy substrates from the fat body (Cheeseman and Goldsworthy, 1979; Orchard and Lange, 1983a; Candy, 2002). The AKH concentration in the hemolymph during flight (Cheeseman and Goldsworthy, 1979; Candy, 2002) is similar to the concentration necessary to induce lipid release from the fat body *in vivo* (Goldsworthy *et al.*, 1986a). In addition to the adipokinetic effect in *L. migratoria*, injection of a CC extract also causes an increase in hemolymph carbohydrate levels in young male locusts whose fat body contains sufficient glycogen stores (Goldsworthy, 1969). In the moth *Manduca sexta*, AKH stimulates glycogen breakdown in larval insects and lipid mobilization

in adults (Siegert and Ziegler, 1983; Ziegler and Schulz, 1986; Ziegler *et al*., 1990).

The similarity of AKH and HrTH was demonstrated before their structures were known; a *P. americana* CC extract induced an adipokinetic response in *L. migratoria* and a *L. migratoria* CC extract induced a hyperglycemic response in *P. americana* (Goldsworthy *et al*., 1972a). The differences in the metabolic responses reflect the strategy of the insect in the nature of the fuel stored in the fat body. An adipokinetic hormone was first identified in *L. migratoria* (Stone *et al*., 1976). The structural similarity of the *L. migratoria* and *P. americana* peptides was confirmed when three groups isolated two octapeptides in the same year from *P. americana* based on myotropic assays (Baumann and Penzlin, 1984; Scarborough *et al*., 1984; Witten *et al*., 1984). However, Scarborough *et al*. (1984) also showed that the less abundant peptide from *P. americana*, Peram-CAH-II (**Figure 1**) has a very significant sequence identity to glucagon (4 of 8 residues are identical; 2 others are highly conserved), and that both peptides would elevate hemolymph carbohydrate in an assay where trehalose is hydrolyzed to glucose. Later Siegert and Mordue (1986a) isolated these factors as specific hypertrehalosemic agents from cockroach. Because of the functional relatedness of AKH peptides, heterologous bioassays, such as the lipid mobilization assay in *L. migratoria* and carbohydrate mobilization assay in *P. americana*, are often used for the isolation of metabolic neuropeptides in a large number of insect species (Gäde, 1980).

The biochemical effect of a CC extract in the *P. americana* fat body is the activation of glycogen phosphorylase (Steele, 1963). Similarly in *L. migratoria*, glycogen phosphorylase is activated by a CC extract (Van Marrewijk *et al*., 1980) or by synthetic AKH (Gäde, 1981). The effect of AKH on lipid mobilization in *M. sexta* is mediated by the activation of triacylglycerol lipase (TAG lipase) which converts TAG into diacylglycerol, which is subsequently released into the hemolymph (Arrese *et al*., 1996). Injection of Locmi-AKH I into *S. gregaria* resulted in a twofold increase of TAG lipase in the fat body (Ogoyi *et al*., 1998).

As is common among neuropeptides, AKH possesses numerous biological activities in addition to its well-known metabolic functions. Some of these actions include the acceleration of heart rate in *P. americana* (Baumann and Gersch, 1982; Scarborough *et al*., 1984) and *Blaberus discoidalis* (Keeley *et al*., 1991), the stimulation of myotropic contractions in *P. americana* (O'Shea *et al*., 1984; Witten *et al*., 1984), the inhibition of protein synthesis

Figure 1 Alignment of sequences of the known AKH/HrTH from the Insecta, from a sample of 39 peptides with a unique primary structure. Peptide sequences were compiled largely from Gäde *et al*. (1997) with the inclusion of additional unique sequences found since 1997 (Gäde and Kellner, 1999; Siegert, 1999; Kodrík *et al*., 2000; Köllisch *et al*., 2000; Siegert *et al*., 2000; Lorenz *et al*., 2001; Gäde *et al*., 2003). The sequence of one peptide from *Carausius morosus* (Carmo-HrTHI*) contains a hexose modification on the Trp8 residue (Gäde *et al*., 1992), and an additional peptide from *Platypleura capensis* (Placa-HrTHI†) contains a modification that has not been characterized (Gäde and Janssens, 1994). Species names are as given in the Swiss-Prot database as recommended previously (Coast *et al*., 2002). Those not defined in the text are: Anaim, *Anax imperator*; Bladi, *Blaberus discoidalis*; Declu, *Decapotoma lunata*; Emppe, *Empusa pennata*; Erysi, *Erythemis simplicicollis*; Grybi, *Gryllus bimaculatus*; Libau, *Libellula auripennis*; Micvi, *Microhodotermes viator*; Onyay, *Onymacris aygulus*; Phote, *Phormia terranova*; Phymo, *Phymateus morbillosus*; Phyle, *Phymateus leprosus*; Polae, *Polyphaga aegyptiaca*; Psein, *Pseudagrion inconspicuum*; Pyrap, *Pyrrhocoris apterus*; Rommi, *Romalea microptera*; Scade, *Scarabaeus deludens*; Tenar, *Tenthredo arcuata*; Vanca, *Vanessa cardui*. The 15 N-terminal residues of glucagon are shown (16–29 deleted); Gln3 is conserved in all AKH and the motif Thr-Phe-Thr from glucagon is 100% conserved in nine sequences, and Ser8 and Asp9 of glucagon are conserved in certain AKH sequences and are conservative substitutions in others. Tyr10 is a conservative substitution for the completely conserved Trp.

(Carlisle and Loughton, 1979; Cusinato *et al.*, 1991) and RNA synthesis (Kodrik and Goldsworthy, 1995), the inhibition of lipid synthesis (Gokuldas *et al.*, 1988), the stimulation of heme synthesis in *B. discoidalis* (Keeley *et al.*, 1991), a neuromodulatory effect in *P. americana* (Wicher *et al.*, 1994), the stimulation of locomotory activity in *M. sexta* (Milde *et al.*, 1995) and *Pyrrhoccoris apterus* (Socha *et al.*, 1999; Kodrík *et al.*, 2000), and a lipogenic effect in which lipids are translocated from the hemolymph to the fat body in *P. americana* (Oguri and Steele, 2003).

Although AKH is widely viewed as an energy mobilization hormone synthesized by and released from the CC, effects on the nervous system have been documented. This was first shown by demonstrating that neurohormone D, an HrTH neuropeptide in *P. americana*, elicits an increase in the spontaneous spike frequency in DUM neurons of the cockroach terminal ganglion (Wicher *et al.*, 1994). This action of neurohormone D on Ca^{2+} currents is through the upregulation of the mid/low voltage activated (M-LVA) Ca^{2+} current by the actions of cAMP and protein kinase A (PKA), suggesting a role for phosphorylation of the channel protein by PKA (Wicher, 2001). The contribution of protein kinase C in the regulation of Ca^{2+} influx through voltage activated Ca^{2+} channels was also documented.

Injection of Manse-AKH into the mesothoracic neuropil increases motor activity in *M. sexta*, similar to the effects of octopamine (Milde *et al.*, 1995). A stimulation of locomotory activity in the firebug, *P. apterus* was observed after injection of Locmi-AKH I or the endogenous peptide, Pyrap-AKH (Socha *et al.*, 1999; Kodrík *et al.*, 2000). The mechanism for the peptide's action on the nervous system was not determined, but dispersal activity is associated with starvation and the need to mobilize energy reserves from the fat body (Socha *et al.*, 1998). Thus, in *P. apterus*, the neuromodulatory function of AKH integrates behavior with the metabolic needs of the insect (Socha *et al.*, 1999). Some investigators reported the presence of Locmi-AKH I in the brain (Moshitzky *et al.*, 1978; Bray *et al.*, 1993). Using mass spectrometric (MS) analysis, none of the Locmi-AKHs were detected in the pars intercerebralis (PI), but a material with the M_r of Locmi-HrTH (Siegert, 1999) was present in the PI and in the CC (Clynen *et al.*, 2001).

The interaction of AKH with both the humoral and cellular immune system was demonstrated in *L. migratoria* (Goldsworthy *et al.*, 2002, 2003a). One component of the insect defense response to wounding and infection is the activation of phenoloxidase via a serine proteinase cascade triggered by the recognition of bacterial and fungal cell wall components resulting in the production of toxic quinones (Gillespie *et al.*, 1997). Injection of Locmi-AKH I or II enhanced the activation of phenoloxidase in response to a challenge with laminarin (a β-1,3-glucan) and activated phenoloxidase in the presence of bacterial lipopolysaccharide (LPS) (Goldsworthy *et al.*, 2002). The different potencies of Locmi-AKH I and II in phenoloxidase activation are consistent with their relative potencies in the locust lipid mobilization assay (Goldsworthy *et al.*, 1986b), suggesting a direct link between the immune and lipid mobilization responses (Goldsworthy *et al.*, 2002). The enhancement of phenoloxidase activation by AKH is age dependent, and restricted to the mature adult stage (Mullen and Goldsworthy, 2003). This time dependence correlates with the lipid mobilization response to AKH (Mwangi and Goldsworthy, 1977a) and to the concentration of apolipophorin III (ApoLp-III) in the hemolymph (Mwangi and Goldsworthy, 1977b; Mullen and Goldsworthy, 2003). In addition to the role of ApoLp-III in lipid metabolism, the lipid associated form of ApoLp-III stimulates antimicrobial activity in the hemolymph of *Galleria mellonella* (Wiesner *et al.*, 1997; Detloff *et al.*, 2001). These data suggest that AKH may be exerting its effect on phenoloxidase activation in part through its effects on ApoLp-III metabolism (Mullen and Goldsworthy, 2003). An effect on phenoloxidase activation by LPS in the absence of AKH was observed in starved locusts, presumably because of the effects of starvation on lipid mobilization (Goldsworthy *et al.*, 2003a).

An important component of the cellular immune response is the formation of nodules by hemocyte aggregation to engulf or entrap foreign bodies (Lavine and Strand, 2002). AKH increases nodule formation when coinjected with LPS (Goldsworthy *et al.*, 2003a). Unlike the effects of AKH on phenoloxidase activation, which is specific to mature locusts (Goldsworthy *et al.*, 2002), its effects on nodule formation are apparent from the fifth instar nymphal stage through the mature adult stage. AKH may be exerting its effect on the humoral immune system (activation of prophenoloxidase) and the cellular immune system (nodule formation) via separate mechanisms, since they exhibit differing sensitivities to pharmacological agents and show different correlations to the nutritional state and lipid composition (Goldsworthy *et al.*, 2003b).

3.10.2.1.2. Structural features of AKH Evidence for multiple AKHs within a species was first found in locusts (Carlsen *et al.*, 1979), and has been extended to include many insect species (Gäde

et al., 1997), with three biologically active peptides present in some insects (Oudejans *et al.*, 1991; Siegert *et al.*, 2000; Köllisch *et al.*, 2003). Each AKH is derived from a unique mRNA (Schulz-Aellen *et al.*, 1989; Noyes and Schaffer, 1990; Fischer-Lougheed *et al.*, 1993; Bogerd *et al.*, 1995). In *L. migratoria*, a fourth member of the AKH family (Locmi-HrTH) was characterized based on its hypertrehalosemic activity in *P. americana*, but no function has yet been identified in *L. migratoria* (Siegert, 1999). The three Locmi-AKHs differ in amount, with Locmi-AKH I being the most abundant and Locmi-AKH III the least abundant (Oudejans *et al.*, 1993; Clynen *et al.*, 2001). One rationale for multiplicity of peptides is their varying potencies in different biological assays, which may enable the fine tuning of an energy-demanding response such as long-distance flight (Vroemen *et al.*, 1998a). Locmi-AKH I and II differ in potency. Locmi-AKH I is more effective than Locmi-AKH II in the lipid mobilization assay, the ability to alter circulating lipoproteins, and the ability to activate glycogen phosphorylase, while Locmi-AKH II is more effective in increasing cAMP levels in the fat body (Orchard and Lange, 1983a; Goldsworthy *et al.*, 1986b). These data suggest that Locmi-AKH I is the predominant hyperlipemic hormone, and Locmi-AKH II is largely responsible for carbohydrate mobilization. Locusts employ carbohydrate as an energy source for the initial stages of flight and lipid for more prolonged flight (Weis-Fogh, 1952; Mayer and Candy, 1969b; Jutsum and Goldsworthy, 1976), suggesting that Locmi-AKH II is most important at the onset of flight and Locmi-AKH I assumes a major role in prolonged flight activity (Vroemen *et al.*, 1997). Locmi-AKH III is present at low levels and seems to have a high turnover, suggesting it may be a modulatory entity that provides the locust with energy when not flying.

The peptides from the AKH family are among the most thoroughly characterized insect peptides with respect to their structural diversity (Gäde *et al.*, 1997). At least 38 distinct peptides have been structurally characterized from at least 90 species that include representatives from most insect orders (**Figure 1**). A distinct sequence of an additional family member, the red pigment-concentrating hormone (Panbo-RPCH), long thought to be unique to crustaceans (Fernlund and Josefsson, 1972), has recently been found in insects (Gäde *et al.*, 2003). RPCH has been shown to induce hyperlipemia in locusts (Herman *et al.*, 1977; Mordue and Stone, 1977). In contrast to the insect peptides whose roles include the mobilization of metabolic stores, the role of RPCH in crustaceans is to induce aggregation of pigment granules in chromatophores (Rao, 2001). Thus, these orthologous peptides found in insects and crustacea do not retain a common function. Although AKH-like immunoreactivity exists in invertebrate phyla other than the Arthropoda (Schooneveld *et al.*, 1987), confirmation of the presence of related peptides is lacking. The most compelling evidence thus far for an AKH related peptide in a nonarthropod is the detection of Locmi-AKH I-like immunoreactivity in the nematode *Panagrellus redivivus* and the induction by a peptide fraction of an adipokinetic response in *S. gregaria* and a hypertrehalosemic response in *P. americana* (Davenport *et al.*, 1991).

All AKH precursor proteins share a common organization; an N-terminal signal peptide followed by AKH and the AKH precursor-related peptide (APRP) (Martínez-Pérez *et al.*, 2002). The organization of the RPCH precursor protein (Linck *et al.*, 1993) is similar to that of AKH/HrTH peptides, supporting the hypothesis that they are derived from a common ancestor (Martínez-Pérez *et al.*, 2002). Close examination of the precursor structures and gene organization of AKH/RPCH peptides with that of the APGWamide peptide family of mollusks revealed similarities including a common overall architecture of the precursor protein, a common predicted secondary structure, and similar position of introns, suggesting that they could have arisen from a common ancestral gene or from recombination of an ancestral AKH/RPCH-like gene with an APGWamide-like gene (Martínez-Pérez *et al.*, 2002).

While significant structural variability was observed when comparing AKH peptides sequenced in different insect species, several common characteristics are defining features of this family (Gäde *et al.*, 1997) (**Figure 1**). The sizes of AKHs range from 8 to 11 amino acids. All AKHs are blocked at their N-terminus with a pyroglutamate residue, and all are amidated at their C-terminus with one exception (Köllisch *et al.*, 2000). An aromatic amino acid is present in each AKH at position 4, and Trp is conserved at position 8. The most critical residues for bioactivity are probably the most prevalent (pGlu1, Phe4, Trp8) and might be involved in binding to the receptor, stability of the peptide, or formation of an intrapeptide interaction stabilizing the conformation needed to achieve optimal activity (Hayes and Keeley, 1990; Gäde, 1992). For example, the conserved Trp8 was proposed to form a hydrogen bond with Ser5 or Phe4 (Hayes and Keeley, 1990), and the hydrophobic nature and relative spacing of residues 2, 4, and 8 may be important in determining receptor binding.

The biological activity of neuropeptides is mediated by their interaction with a membrane bound receptor on the target cell; most then alter the concentration of second messengers that result in biochemical changes and ultimately lead to a physiological response. Small peptides, such as AKH, are flexible structures that adopt many conformations in solution, and their potency is related to their structural conformation upon interaction with the receptor (Nachman *et al.*, 1993). The identification of AKH receptors and their expression allows the direct assay of peptide (or analog) binding to the receptor and subsequent response of the target cell to identify the critical structural features of the peptides that are required for receptor binding and activation. However, considerable information on the importance of individual amino acids or parts of the peptide for binding to the receptor has been acquired using bioassays in structure–activity studies in several insect species, but these results are also influenced by such factors as the relative stability of the peptides *in vivo*. The overall conclusion that can be drawn from structure–activity studies is that the endogenous peptides are usually the most potent in the respective bioassays, and coevolution of the peptide and the receptor took place to achieve optimal binding (Hayes and Keeley, 1990; Fox and Reynolds, 1991a).

Stone *et al.* (1978) predicted that many members of the AKH/RPCH family have the potential to adopt a β-turn conformation. While AKH peptides do not form an ordered structure in aqueous solution, the presence of sodium dodecylsulfate (SDS) causes a change in the circular dichroism (CD) spectra that is characteristic of a β-turn (Goldsworthy and Wheeler, 1989; Cusinato *et al.*, 1998). However, the CD spectra of Locmi-AKH II and Manse-AKH, peptides that lack a proline residue in position 6, are not affected by the presence of SDS and lack the capacity to form a β-turn. The capacity of some AKH peptides to form a β-turn between residues 4 and 8 was also confirmed using nuclear magnetic resonance (NMR) spectroscopy (Zubrzycki and Gäde, 1994; Zubrzycki and Gäde, 1999; Nair *et al.*, 2001). It was suggested that the activity of AKH in the *L. migratoria* lipid mobilization assay is correlated with the ability to form a β-structure in SDS micelles, which in turn quantitatively affects its interactions with the receptor (Goldsworthy *et al.*, 1997; Cusinato *et al.*, 1998). Locmi-AKH II and Manse-AKH, which lack the ability to form a β-structure, exhibit low potency in the *L. migratoria* lipid mobilization assay (Cusinato *et al.*, 1998). Analogs with substitutions in residues 6–8 of AKHs exhibit reduced potency since the substitutions apparently hinder the formation of a β-turn (Lee *et al.*, 1996). However, the capacity to form a β-turn does not correlate with potency when assayed for inhibition of acetate uptake into fat body *in vitro*, since *Acheta domesticus* AKH and Locmi-AKH II are equally active using this assay (Cusinato *et al.*, 1998). This pleiotropic response may reflect the heterogeneity of receptors, which exhibit differing structural preferences for their ligand. Structural analysis of AKH peptides from *Melolontha melolontha* (Melme-CC), *Tenebrio molitor* (Tenmo-HrTH), and *Decapotoma lunata* (Declu-CC) using NMR supports the hypothesis that the β-turn is important for receptor binding in the *L. migratoria* lipid mobilization assay (Nair *et al.*, 2001). The Asn residue at position 7 (Asn7), and the Phe residue at position 4 (Phe4) are essential for a potent response, and it was shown that the Asn7 projects outward from the β-turn, and the orientation of Asn7 and the tightness of the β-turn are influenced by the aromatic residue at position 4. Data on the biological activity of a large number of natural AKHs and synthetic analogs in the *L. migratoria* lipid mobilization assay and acetate uptake assay were compiled to attempt to construct quantitative structure–activity relationships (QSAR) (Lee *et al.*, 2000). Little new understanding was gained in this study since the peptides used were not designed with QSAR in mind, but this approach might be used to understand the requirements of peptide–receptor interactions and to predict sequences that possess improved biological potency as used successfully with substance P (Norinder *et al.*, 1997).

Structure–activity studies were also carried out using the activation of glycogen phosphorylase in *M. sexta* fat body to assay several naturally occurring AKH peptides and synthetic analogs (Ziegler *et al.*, 1991, 1998). Manse-AKH lacks the ability to form a β-turn (Goldsworthy and Wheeler, 1989), and among the peptides tested, the most inactive were the ones with the highest probability of forming a β-turn (Ziegler *et al.*, 1991, 1998). The substitution of Ser6 of Manse-AKH with Pro, which favors the formation of a β-turn, drastically reduced its abilities to activate glycogen phosphorylase and to bind to the receptor in a fat body membrane preparation. This indicates that the *M. sexta* AKH receptor does not bind peptides that contain a β-turn (Ziegler *et al.*, 1998).

Removal of pGlu1 from Locmi-AKH I abolishes activity (Gäde, 1990), but replacement of pGlu1 by an unblocked amino acid partially restored lipid mobilization activity *in vivo* to varying degrees depending on the identity of the substituted amino acid, and activity was further enhanced by N-terminal blockage (Lee *et al.*, 1997). Replacement of pGlu1 in

Manse-AKH, however, did not restore potency in a bioassay measuring activity of glycogen phosphorylase unless the N-terminus was blocked (Herman *et al.*, 1977; Ziegler *et al.*, 1998). These data imply that pGlu1 is not absolutely essential for activity, and that one of the roles of the blocked N-terminus might be to impart increased stability to the peptide by preventing aminopeptidase attack (Lee *et al.*, 1997; Ziegler *et al.*, 1998).

3.10.2.1.3. AKH synthesis and release Like most neuropeptides, AKH is derived by processing of a larger precursor protein (Hekimi and O'Shea, 1987). The steps involved in AKH synthesis have been most thoroughly characterized in *S. gregaria* (O'Shea and Rayne, 1992), and subsequent studies in other insects have shown that the basic features of AKH biosynthesis are conserved. AKH precursor proteins share a similar organization, an N-terminal signal peptide, followed by AKH and the AKH precursor related peptide (APRP) (O'Shea and Rayne, 1992), as first shown in *S. gregaria* (Schulz-Aellen *et al.*, 1989) and *M. sexta* (Bradfield and Keeley, 1989). The locust AKH precursor exists as a dimer formed by oxidation of the Cys residues present in the APRP. This occurs prior to proteolytic processing in the trans-Golgi at basic amino acid residues and C-terminal amidation (Rayne and O'Shea, 1994). The dimeric structure of the precursor might confer a conformation that facilitates or allows the correct processing of the precursor. Since multiple AKHs (Diederen *et al.*, 1987; Hekimi *et al.*, 1991) and their mRNAs (Bogerd *et al.*, 1995) are present in the same glandular cells, random formation of dimeric precursors gives rise to both homodimers and heterodimers (Hekimi *et al.*, 1991; Huybrechts *et al.*, 2002). Further processing of *L. migratoria* APRPs from the AKH I and AKH II precursors takes place to yield additional peptides designated the adipokinetic hormone joining peptides (AKH-JP I and AKH-JP II), but their release was not demonstrated (Baggerman *et al.*, 2002). Biological roles for the APRPs or the AKH-JPs have not been found (Oudejans *et al.*, 1991; Hatle and Spring, 1999; Baggerman *et al.*, 2002). Relative peptide levels in the glandular cells are controlled by multiple mechanisms. The 4.5:1 ratio of AKH I to AKH II present in the glandular cells (Hekimi *et al.*, 1991) is regulated by a 1.7:1 ratio of AKH I to AKH II mRNA and the more efficient translation of AKH I mRNA (Fischer-Lougheed *et al.*, 1993).

Antisera specific to AKH I or AKH II have demonstrated their colocalization in the same secretory granules in the glandular cells of the CC (Diederen *et al.*, 1987). Since an AKH III-specific antiserum is not available, the colocalization of each APRP implies that AKH III is also colocalized with AKH I and II (Harthoorn *et al.*, 1999). The amount of AKHs increase dramatically in the CC during development (Siegert and Mordue, 1986b), due to their continued synthesis (Fischer-Lougheed *et al.*, 1993; Oudejans *et al.*, 1993) and to the increase in the number of cells in the glandular lobe of the CC (Kirschenbaum and O'Shea, 1993). The continued synthesis of AKH generates a large pool of secretory granules in the glandular cells (Diederen *et al.*, 1992), and newly synthesized AKH is preferentially released over AKHs stored in older secretory granules (Sharp-Baker *et al.*, 1995), which constitutes a pool of peptides that cannot be released (Sharp-Baker *et al.*, 1996; Harthoorn *et al.*, 2002). Therefore, only a small percentage of the total AKH present in the glandular cells is released during flight (Cheeseman *et al.*, 1976) or upon stimulation by CCAP (Harthoorn *et al.*, 2002). The AKHs are released in the same proportion as their levels in the CC (Harthoorn *et al.*, 1999), and the continuous synthesis of AKH is required for the secretion of peptides from the glandular cells in response to metabolic need (Harthoorn *et al.*, 2002).

In *S. gregaria* and *L. migratoria*, the hemolymph trehalose levels during flight are about 50% that of preflight values (Mayer and Candy, 1969b; Jutsum and Goldsworthy, 1976), and injection of a high concentration of trehalose prevents AKH release assayed by quantifying lipid mobilizing activity in the hemolymph (Cheeseman *et al.*, 1976). Trehalose and glucose exert a direct action on the glandular cells of the CC, since high trehalose concentrations decreased both spontaneous AKH release and AKH release induced by the neuropeptide Locmi-TK I, 3-isobutyl-l-methylxanthine (IBMX), or high potassium concentrations *in vitro* (Passier *et al.*, 1997). It was suggested that trehalose exerts this effect, in part, after its conversion to glucose. The decrease in trehalose concentration in response to the energy demands of flight relieves this inhibition, and is one of the factors that contributes to AKH release that is observed during flight (Cheeseman and Goldsworthy, 1979; Orchard and Lange, 1983b). It was also suggested that high levels of diacylglycerol resulting from mobilization of lipid energy stores may exert negative feedback on AKH release (Cheeseman and Goldsworthy, 1979).

The neural and hormonal factors that modulate AKH release have been most thoroughly characterized in *L. migratoria* (Vullings *et al.*, 1999). Implanted CC do not show the ultrastructural signs of enhanced AKH release during flight, suggesting that AKH secretion is under neural control by cells

that make direct contact with the glandular lobe cells (Rademakers, 1977a). Neuroanatomical studies defined the secretomotor neurons in the lateral part of the protocerebrum that project through the nervi corporis cardiaci II (NCC II) to innervate the glandular lobe of the CC (GCC) and make synaptic contact with the AKH cells, and the axon terminals of the GCC are derived solely from the secretomotor cells (Rademakers, 1977b; Konings *et al.*, 1989). Electrical stimulation of the NCC II resulted in the release of AKH I and II from the GCC and was accompanied by an increase in cAMP levels in cells of the GCC (Orchard and Loughton, 1981; Orchard and Lange, 1983a). While stimulation of the NCC I had no direct effect on AKH release, an enhancement of the NCC II-stimulated release of AKH from the CC was observed (Orchard and Loughton, 1981). Hormonally mediated lipid mobilization during flight is abolished in locusts in which the NCC I and NCC II were severed (Goldsworthy *et al.*, 1972b). Together, these data indicate that the secretomotor neurons are involved in the control of AKH release, and compounds present in the NCC I modulate AKH secretion.

An antiserum raised against locustatachykinin I (Locmi-TK I), a member of a family of structurally related neuropeptides (Schoofs *et al.*, 1993), stained a subset of secretomotor neurons projecting to the GCC and made synaptoid contacts with AKH-immunoreactive glandular cells, suggesting a role for a Locmi-TK I-like peptide in AKH release (Nässel *et al.*, 1995). Indeed, Locmi-TK I and II induced AKH release from the CC *in vitro* and increased cAMP levels in the GCC, but an effect on AKH release required concentrations in the 50–200 μM range (Nässel *et al.*, 1995, 1999). Furthermore, four Locmi-TK isoforms were identified in *L. migratoria* CC extracts (Nässel *et al.*, 1999). The anatomical features of the Locmi-TK-containing secretomotor neurons suggest that these peptides might act on synaptic receptors, and the high concentration of peptide required for AKH release is consistent with this hypothesis, particularly since synaptic receptors might be less accessible for an *in vitro* effect and thus would require higher peptide concentrations for an effect to be observed.

SchistoFLRFamide is a member of a large family of neuropeptides known as the FMRFamide-related peptides (FaRPs) that are widely found in insects (Orchard *et al.*, 2001). Antisera to FMRFamide and SchistoFLRFamide label a subset of secretomotor neurons that are distinct from the Locmi-TK-containing cells which make synaptoid contacts with glandular cells of the CC (Vullings *et al.*, 1998). FMRFamide and SchistoFLRFamide have no effect on the spontaneous release of AKH *in vitro*, but reduced IBMX-induced AKH release at a 10 μM peptide concentration. Like the case with Locmi-TK neuropeptides, the high concentration of FaRPs required for an effect is consistent with a direct supply of peptides on the glandular cells. Thus, FaRPs are inhibitory neuromodulators that act to fine-tune the release of AKH to meet the energetic demands of the flying animal (Vullings *et al.*, 1998).

A direct approach was used to isolate a compound, the neuropeptide CCAP, from a *S. gregaria* brain extract that potently stimulates release of AKH from *L. migratoria* and *S. gregaria* CC *in vitro* (Veelaert *et al.*, 1997). CCAP is a multifunctional neuropeptide and is best known for its stimulatory activity on heartbeat (Tublitz and Truman, 1985) and its effect as trigger for ecdysis behavior (Gammie and Truman, 1997; see **Chapter 3.1**). Unlike the Locmi-TK and SchistoFLRFamide-like peptides, there are no CCAP containing fibers in the GCC (Dircksen and Homberg, 1995; Veelaert *et al.*, 1997); CCAP is active in the nM range indicating that it may act as a neurohormonal releasing factor for AKH (Veelaert *et al.*, 1997).

Flight activity increases the octopamine levels in the hemolymph of *S. gregaria* (Goosey and Candy, 1980), and in *L. migratoria*, octopamine was shown to stimulate AKH release from the CC in the presence of IBMX (Pannabecker and Orchard, 1986). It was later found that in this experimental design, octopamine potentiates the stimulatory effect of IBMX mediated cAMP elevation on AKH release, and has no effect on its own (Passier *et al.*, 1995). This suggests that octopamine has a neurohormonal role in modulating AKH release (Veelaert *et al.*, 1997).

3.10.2.1.4. AKH degradation After secretion of AKHs into the hemolymph, their degradation will have a significant effect on peptide levels, and the differential rates of degradation will affect the ratios of peptides and, ultimately, the physiological response. AKHs are blocked at both termini, and the initial step in their degradation is by an endopeptidase that yields inactive peptide fragments (Siegert and Mordue, 1987; Fox and Reynolds, 1991b; Rayne and O'Shea, 1992). The endopeptidase has been localized to the external surface of several tissues (Rayne and O'Shea, 1992), including the Malpighian tubules (Baumann and Penzlin, 1987; Siegert and Mordue, 1987), but in *M. sexta*, AKH is cleaved by an enzyme circulating in the hemolymph (Fox and Reynolds, 1991b).

The half-life of AKH I in *L. migratoria* was initially determined to be 24 min by quantifying the disappearance of AKH from the hemolymph subsequent to its release using an *in vivo* bioassay (Cheeseman

et al., 1976). Subsequently, a half-life of 30 min was determined for AKH I and II in *S. gregaria* by measuring the disappearance of AKH after injecting a large, nonphysiological dose (Rayne and O'Shea, 1992). The synthesis of high-specific activity tritiated AKHs allowed the quantification of the half-lives of AKH I, II, and III in *L. migratoria* after injecting a physiological dose of 1 pmol (Oudejans *et al.*, 1996). This study clearly demonstrated that each AKH has a different rate of breakdown, with AKH III being significantly less stable in the hemolymph. The half-lives of AKH I, II, and III at rest are 51, 40, and 5 min, respectively, and AKH I and III are degraded more rapidly during flight, suggesting that more than one protease is involved in AKH degradation. In contrast to the relatively long half-lives of Locmi-AKH I and II, injected *Gryllus bimaculatus* AKH has a half-life of about 3 min and is degraded by enzymes released from hemocytes (Woodring *et al.*, 2002).

3.10.2.1.5. Signal transduction for AKH There is substantial evidence from a number of systems that inositol-1,4,5-trisphosphate (IP_3) serves as the second messenger to transduce the hormonal signal of AKH/HrTH neuropeptides in the fat body and, in some cases, cAMP is also involved (Van der Horst *et al.*, 1997; Gäde and Auerswald, 2003). In *L. migratoria*, the involvement of cAMP in AKH mediated lipid mobilization was shown by demonstrating the accumulation of cAMP in the fat body following an injection of a CC extract, and the increased hemolymph lipid concentration after treatment with dibutyryl-cAMP (db-cAMP) (Gäde and Holwerda, 1976). A similar effect of a CC extract on cAMP levels was also shown *in vitro* in *S. gregaria* (Spencer and Candy, 1976). The effect of the CC extract on cAMP levels was shown to be due to AKH (Gäde, 1979; Goldsworthy *et al.*, 1986b).

Although the mobilization of lipids is a crucial role of AKH in *L. migratoria*, the mechanism of AKH action in the target cell has been studied most extensively using glycogen phosphorylase activation as the assay for AKH activity (Van Marrewijk *et al.*, 1980). The potencies of each AKH in cAMP elevation and glycogen phosphorylase activation differed when assayed at physiological levels, decreasing in the order AKH III > AKH II > AKH I (Vroemen *et al.*, 1995a). These differences in potency support the hypothesis that the action of AKH II is more directed to carbohydrate metabolism than that of AKH I (Orchard and Lange, 1983a). The increase in cAMP levels is mediated by the G protein G_s, since cholera toxin, an irreversible activator of G_s, enhanced cAMP levels and glycogen phosphorylase activity (Vroemen *et al.*, 1995a). Pertussis toxin, an irreversible inhibitor of G_i, had no effect on cAMP levels or glycogen phosphorylase activation.

In *L. migratoria*, the uptake of Ca^{2+} into the fat body was stimulated by the presence of AKH, and the effects of AKH on diacylglycerol levels and glycogen phosphorylase activation are dependent on extracellular Ca^{2+} and can be mimicked by the calcium ionophore A23187 (Van Marrewijk *et al.*, 1991). A similar Ca^{2+} dependence for AKH mediated lipid mobilization was demonstrated *in vitro* (Lum and Chino, 1990; Wang *et al.*, 1990). In addition, the release of Ca^{2+} from intracellular stores leads to the subsequent influx of Ca^{2+} into the cell (Van Marrewijk *et al.*, 1993) by a process known as capacitative Ca^{2+} entry (Berridge, 1995), confirming a requirement for both intracellular and extracellular Ca^{2+} for the full effect of AKH on the fat body. Although each of the three AKHs increase Ca^{2+} uptake with similar potency, the three AKHs also enhance the efflux of Ca^{2+} into the fat body cytosol, but the increase in efflux increased in the order AKH I < AKH II < AKH III (Vroemen *et al.*, 1995b), so the effect of AKH I on intracellular Ca^{2+} levels that result from flux across the cell membrane is the greatest of the three AKHs. The mobilization of intracellular Ca^{2+} by each of the AKHs in locusts is mediated by the stimulation of inositol phosphate (InsPn) formation, most notably IP_3 (Stagg and Candy, 1996; Van Marrewijk *et al.*, 1996), but differences in potency were documented for each AKH in *L. migratoria*, decreasing in the order AKH III > AKH I > AKH II (Vroemen *et al.*, 1997). IP_3, generated by activation of phospholipase C (PLC), plays a critical role in Ca^{2+} mobilization that leads to activation of protein kinase C (PKC) for a wide variety of neuropeptides (Berridge, 1993). The stronger effect of AKH I on IP_3 combined with its weak effect on Ca^{2+} efflux relative to AKH II suggest that AKH I is the major lipid mobilizing hormone, particularly since Ca^{2+} is required for translocation of hormone sensitive lipases from the cytosol to lipid droplets to elicit lipolysis (Clark *et al.*, 1991; Egan *et al.*, 1992). The activation of glycogen phosphorylase by each of the AKHs is mediated by PLC activation, since a PLC inhibitor, U73122, dampened the response to the peptides, and the residual activity might be due to a cAMP pathway not influenced by IP_3 (Vroemen *et al.*, 1997). Elevation of IP_3 levels by AKH is mediated by the G protein G_q, since a G_q antagonist dampened AKH I induced glycogen phosphorylase activity (Vroemen *et al.*, 1998b). Stimulation of glycogen phosphorylase by cAMP is independent of extracellular Ca^{2+} (Van Marrewijk *et al.*, 1993), and the elevation of cAMP by forskolin or db-cAMP did not affect the enhancement of InsPn levels by AKH I, so a direct linkage between

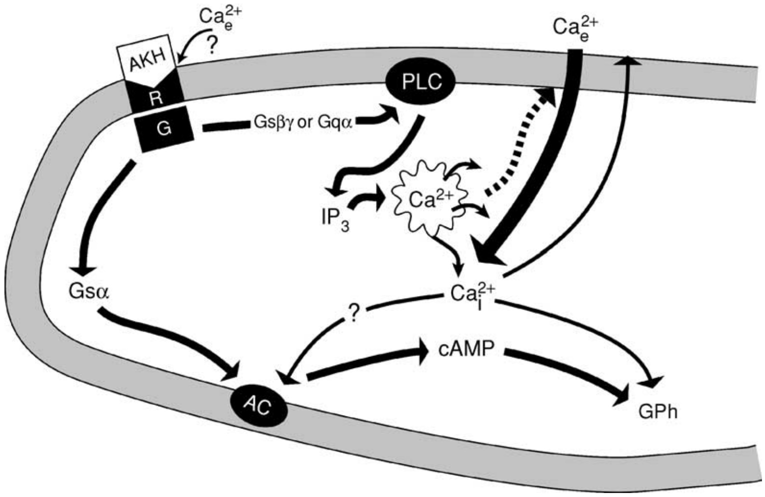

Figure 2 Proposed model for the coupling of AKH signaling pathways in *Locusta migratoria* fat body cells for carbohydrate mobilization. R, receptor; G, G protein; PLC, phospholipase C; IP_3, inositol-1,4,5-trisphosphate; AC, adenylate cyclase; GPh, glycogen phosphorylase. (Reprinted from Van der Horst,D.J., Vroemen, S.F., Van Marrewijk, W.J.A., **1997**. Metabolism of stored reserves in insect fat body: hormonal signal transduction implicated in glycogen mobilization and biosynthesis of the lipophorin system. *Comp. Biochem. Physiol. 117B*, 463–474, with permission from Elsevier.)

the AKH receptor and PLC activation must exist that is not dependent on the elevation of cAMP. These data have led to a model describing AKH signaling in *L. migratoria* (Van der Horst *et al*., 1997) (**Figure 2**). The AKH receptor is coupled to at least two distinct G proteins, G_s and G_q, and the activation of both pathways results in a complete enhancement of glycogen phosphorylase activation by AKH. AKH induced Ca^{2+} influx is mediated by voltage independent channels, possibly calcium release activated channels, since La^{3+}, a universal Ca^{2+} channel blocker, prevents glycogen phosphorylase activation (Vroemen *et al*., 1998b).

In *P. americana*, the effects of HrTH on phosphorylase activation in the fat body and trehalose release are dependent on the presence of extracellular Ca^{2+} (McClure and Steele, 1981; Orr *et al*., 1985; Steele and Paul, 1985), and the entry of Ca^{2+} into intact fat body (Steele and Paul, 1985), or fat body trophocytes (Steele and Ireland, 1999), is stimulated by HrTH. A key role for Ca^{2+} in glycogen breakdown is its requirement, together with calmodulin, for the activity of phosphorylase kinase, the activator of glycogen phosphorylase (Pallen and Steele, 1988). The mode of HrTH action in *P. americana* was examined in disaggregated trophocytes, the fat body cells responsible for trehalose synthesis (Steele and Ireland, 1994). This system was used to provide the ability to test the effect of peptides or varying conditions on a large number of samples to better correlate changes in a discrete population of responsive cells. It was demonstrated that in *P. americana* HrTH I and II stimulated IP_3 formation with comparable potencies (Steele *et al*., 2001). The HrTH stimulated formation of IP_3 and the increase in intracellular Ca^{2+} concentration are probably involved in phosphorylase activation and trehalose efflux from trophocytes, since a PLC inhibitor blocked these effects. HrTH I and II increase Ca^{2+} levels in fat body trophocytes by the release of intracellular Ca^{2+} followed by the subsequent capacitative influx of extracellular Ca^{2+} (Sun and Steele, 2001). Capacitative Ca^{2+} entry is inhibited by activation of protein kinase C or inhibition of calmodulin (Sun and Steele, 2001). HrTH stimulates the activity of phospholipase A_2 in trophocytes (Sun and Steele, 2002), which leads to the increased production of free fatty acids to provide an essential source of energy for trehalose synthesis (Ali and Steele, 1997). Phospholipase A_2 activation and the stimulation of trehalose efflux are dependent on G proteins, protein kinase C and calmodulin, and occur following the increase in cytosolic Ca^{2+} mediated by HrTH (Sun *et al*., 2002; Sun and Steele, 2002). In *P. americana*, a CC extract elevated cAMP levels in the fat body, but this effect was not due to the action of HrTH (Orr *et al*., 1985).

Transduction of the HrTH signal in *B. discoidalis* does not involve cyclic AMP, since HrTH does not elevate fat body cAMP levels (Park and Keeley, 1995), and elevating cAMP levels by IBMX or db-cAMP treatment does not lead to elevated trehalose synthesis (Lee and Keeley, 1994) or glycogen phosphorylase activity (Park and Keeley, 1995). Likewise, no effect of cAMP on trehalose production was observed in the cockroaches *P. americana* (Orr *et al*., 1985) or *Blaptica dubia* (Becker *et al*., 1998).

The release of Ca^{2+} from intracellular stores by thimerosal or thapsigargin increased trehalose synthesis (Keeley and Hesson, 1995) and glycogen phosphorylase activation (Park and Keeley, 1996), even in the absence of extracellular Ca^{2+}. In contrast, stimulation of the influx of extracellular Ca^{2+} did not affect trehalose synthesis (Keeley and Hesson, 1995) and had only a modest effect on phosphorylase activation (Park and Keeley, 1996). However, a maximal response to hormone requires the presence of extracellular Ca^{2+} (Keeley and Hesson, 1995; Park and Keeley, 1996). Since HrTH was shown to increase IP_3 levels in the fat body, it was suggested that HrTH leads to the release of intracellular Ca^{2+} followed by an influx of extracellular Ca^{2+} to achieve a maximal effect on the fat body (Park and Keeley, 1996). A similar dependence on extracellular and intracellular Ca^{2+} was demonstrated for HrTH mediated trehalose production in *B. dubia* (Becker *et al.*, 1998). However, the HrTH mediated decrease in concentration of the metabolic signaling molecule, fructose 2,6-bisphosphate (Becker and Wegener, 1998), is largely dependent on Ca^{2+} entry, since this effect could be fully mimicked by the calcium ionophore A23187 (Becker *et al.*, 1998). This decrease in fructose 2,6-bisphosphate (Becker and Wegener, 1998) is a key regulatory step towards the inhibition of glycolysis and directing the products of glycogen breakdown towards the production of trehalose that results from HrTH action (Wiens and Gilbert, 1967).

The signal transduction pathway for the action of AKH on lipid mobilization in adult *M. sexta* involves both cAMP and Ca^{2+} (Arrese *et al.*, 1999). The magnitude of diacylglycerol mobilization that was induced by Ca^{2+} mobilizing agents was similar to the response to the peptide, while treatments that increase cAMP levels did not induce a maximal response. For this reason, it was proposed that Ca^{2+} potentiates the action of cAMP. AKH induces an increase in PKA activity that precedes the activation of TAG lipase and release of diacylglycerol, further supporting the role for cAMP as a second messenger for AKH action in *M. sexta*.

In the fruit beetle, *Pachnoda sinuata*, which mobilizes carbohydrate reserves and increases proline synthesis in response to AKH (Auerswald *et al.*, 1998), the signal transduction pathway involves both cAMP and Ca^{2+} (Gäde and Auerswald, 2003). Injection of the endogenous AKH, Melme-CC (first isolated from *M. melolontha*), elevates cAMP levels in the fat body, and injection of a membrane-permeable cAMP analog or IBMX elevates proline levels in the hemolymph supporting the involvement of cAMP (Auerswald and Gäde, 2000). The induction of cAMP by AKH requires the presence of extracellular Ca^{2+} (Auerswald and Gäde, 2001a), and results in the rapid influx of Ca^{2+} into the fat body cell (Auerswald and Gäde, 2001b). The release of intracellular Ca^{2+} is required for the full stimulation of proline production by stimulating the influx of extracellular Ca^{2+} by capacitative Ca^{2+} entry (Auerswald and Gäde, 2001a). In contrast to the effect of cAMP on proline production, it is not involved in carbohydrate mobilization or glycogen phosphorylase activation (Auerswald and Gäde, 2000), which requires the presence of extracellular Ca^{2+} and the release of Ca^{2+} from intracellular stores (Auerswald and Gäde, 2001b). Injection of Melme-CC causes an increase in IP_3 levels in the fat body, but coinjection with a PLC inhibitor, U73122, affects only the carbohydrate mobilizing activity, and not the hyperprolinemic effect of the peptide (Auerswald and Gäde, 2002). These data suggest that two separate pathways exist for AKH action in *P. sinuata*, and that the release of the IP_3 dependent Ca^{2+} stores from the endoplasmic reticulum is not involved in proline production.

3.10.2.1.6. AKH receptor The *M. sexta* AKH receptor was characterized using tritium labeled Manse-AKH with a binding assay to larval fat body membrane preparations (Ziegler *et al.*, 1995). Specific and saturable binding, which required the presence of Ca^{2+}, was detected with a K_d of 7×10^{-10} M and was consistent with binding to one type of receptor. Smaller amounts of peptide are needed for a full response in a bioassay indicating that only a fraction of receptors must bind peptide for a maximal response. Specific binding to membrane preparations of *M. sexta* heart and muscle was not detected, but a low level of specific binding to the pterothoracic ganglion membrane preparations of adult *M. sexta* was observed (Ziegler *et al.*, 1995), consistent with the action of AKH that was observed on central nervous system neurons (Milde *et al.*, 1995).

Two independent methods were used to identify the AKH receptor cDNA from *D. melanogaster* (Park *et al.*, 2002; Staubli *et al.*, 2002). In one study, the *D. melanogaster* receptor cDNA related to the gonadotropin releasing hormone (GnRH) receptor (AF077299) (Hauser *et al.*, 1998) was expressed in a CHO cell line expressing the promiscuous G protein G16 (CHO/G16) and aequorin, and Drome-AKH was identified as the ligand present in a 3rd instar larval extract that induced a bioluminescent response (Staubli *et al.*, 2002). A dose–response curve showed that the response induced by synthetic Drome-AKH had an EC_{50} of 8×10^{-10} M, and all other *D. melanogaster* peptides tested were inactive.

The *D. melanogaster* AKH receptor was independently identified by injecting *in vitro* synthesized

RNA encoding the GPCR from the vasopressin receptor group (AF522194) into *Xenopus* oocytes and measuring the inward current in response to application of AKH (Park *et al.*, 2002). Oocytes responded specifically to Drome-AKH with an EC_{50} of 3×10^{-10} M. *Xenopus* oocytes expressing a second GPCR (AF522188) reacted with AKH, but with a much lower potency ($EC_{50} = 2.4 \times 10^{-8}$ M). AF522188 also reacted with CCAP with an EC_{50} of 1.2×10^{-8} M suggesting that this GPCR might interact with multiple ligands. This suggestion is supported by the overlap in the functions of AKH and CCAP, since both peptides possess cardioacceleratory activity (Scarborough *et al.*, 1984; Witten *et al.*, 1984; Tublitz and Truman, 1985). The *D. melanogaster* AKH receptors independently identified are derived from the same gene, and differ only by a small deletion of 8 bp in AF522194 causing a frameshift in its predicted sequence at the C-terminus, and several point mutations, only one of which results in an amino acid substitution (Park *et al.*, 2002). These differences did not affect the potency and specificity of their interactions with Drome-AKH.

The characterization of an AKH receptor cDNA in one species leads towards the development of strategies to identify the AKH receptor in a wide variety of insect species (Staubli *et al.*, 2002). Primers were designed to conserved regions of the *D. melanogaster* AKH receptor and a second receptor, that for *D. melanogaster* corazonin (Park *et al.*, 2002), to clone the AKH receptor from *Bombyx mori* (Staubli *et al.*, 2002). Aequorin expressing CHO/G16 cells transfected with the *B. mori* AKH receptor cDNA were activated by Helze-HrTH (Jaffe *et al.*, 1988), a peptide not yet identified in *B. mori*, with an EC_{50} of 3×10^{-10} M. The known AKH from *B. mori* (Ishibashi *et al.*, 1992), identical to Manse-AKH and Helze-AKH, activated the *B. mori* AKH receptor at a lower affinity, suggesting that *B. mori* possesses a second AKH that is more related to Helze-HrTH.

The presence of multiple AKH peptides in many insect species (Gäde *et al.*, 1997), the differing rank order of potencies of these AKHs depending on the assay used (Goldsworthy *et al.*, 1986b), and the age related changes in sensitivity to AKHs (Mwangi and Goldsworthy, 1977a; Ziegler, 1984; Woodring *et al.*, 2002) raise the question of whether AKH(s) interacts with multiple receptors. The presence of multiple AKH receptors in some insect species has been suggested based on biphasic responses to peptide analogs (Gäde and Hayes, 1995). In *P. sinuata*, AKH probably acts through two receptors, since peptide analogs possess differential effects on carbohydrate mobilization and proline synthesis (Auerswald and Gäde, 1999), and these biochemical effects are independently mediated by different signal transduction pathways (Auerswald and Gäde, 2000, 2002). However, evidence in *M. sexta* is consistent with the presence of one type of receptor responsible for the adipokinetic response, since analogs that are partial agonists are capable of reducing the response to the endogenous peptide (Fox and Reynolds, 1991a), and none of the AKH analogs tested exhibited a biphasic response, which would provide evidence for multiple receptors (Ziegler *et al.*, 1998).

Receptor desensitization, the increase in refractoriness in response to sustained exposure to the ligand, is mediated by phosphorylation of the agonist-bound receptor by G protein-coupled receptor kinases (Perry and Lefkowitz, 2002). Preincubation of *L. migratoria* fat body with any of the three Locmi-AKHs renders the tissue insensitive to each of the AKHs (Vroemen *et al.*, 1998a). While this result might imply that all three AKHs share the same receptor, an alternative interpretation is that each receptor recognizes all three AKHs with differing affinities, and that prolonged preincubation with a high dose of one peptide could desensitize all receptors.

3.10.2.1.7. Effects on gene expression Flight activity is the only natural stimulus known for AKH release, but neither AKH mRNA levels nor prohormone synthesis were altered by flight activity (Harthoorn *et al.*, 2001). Therefore, the availability of releasable AKH is dependent on its continuous biosynthesis.

The first example of the regulation of HrTH gene expression by nutritional status was obtained in *B. discoidalis* (Lewis *et al.*, 1998). It was demonstrated that starvation induced a twofold increase in HrTH mRNA levels in the CC, which returned to essentially normal levels after 2 days of refeeding. This starvation induced increase in HrTH mRNA level is accompanied by a similar increase in HrTH synthesis (Sowa *et al.*, 1996). The downregulation of HrTH mRNA levels by feeding is not simply a response to elevated hemolymph carbohydrate levels or a neural response to feeding, but is more likely due to the consumption of a complex of nutrients (Lewis *et al.*, 1998).

The first example of an effect on downstream gene expression in response to an insect neuropeptide (HrTH) was demonstrated in the fat body of *B. discoidalis* (Bradfield *et al.*, 1991). The mRNA level of a cytochrome P450 (P4504C1) was increased directly in response to physiological levels of HrTH, and was also upregulated by starvation in a CC-dependent manner (Bradfield *et al.*, 1991; Lu

et al., 1995, 1996). It was suggested that P4504C1 is involved in mobilization of fat body resources in response to starvation either by the control of fatty acid oxidation to provide energy for the conversion of glycogen to trehalose in response to the release of HrTH (Bradfield *et al.*, 1991), or by providing an alternative route for carbohydrate synthesis during exposure to HrTH or starvation (Lu *et al.*, 1996).

3.10.2.2. A Counter-Regulatory Hormone for AKH?

Despite extensive research, until recently there was no evidence for a counter-regulatory hormone for the AKH family. Bombyxin is an insect homolog of insulin, both in structural properties (Kawakami *et al.*, 1989) and receptor architecture and properties (Fullbright *et al.*, 1997). However, treatment of the natural host with bombyxin results in an activation of glycogen phosphorylase and a decrease in glycogen stores (Satake *et al.*, 1997), the opposite of the effects of insulin in vertebrates. An important role of insulin in vertebrates is lowering blood glucose, to not only maximize the utility of this expensive fuel for anaerobic metabolism, but to prevent damage to body proteins via formation of aldimines from the less abundant, but reactive, aldose form of glucose. Aldimines can rearrange to ketimines, which cannot hydrolyze like aldimines and thus permanently alkylate proteins with adverse effects. Because insect hemolymph contains the nonreducing sugar trehalose, this function of insulin would be of no importance to insects. Clynen *et al.* (2003a) used proteomic techniques to identify a small peptide, QSDLFLLSPK, from the GCC of *L. migratoria*; the mass spectral sequence was ambiguous, because this technique is unable to distinguish Leu from Ile, or Gln from Lys. However, a basic local alignment search tool (BLAST) search revealed a 100% match to a fragment of the locust insulin related peptide (Lagueux *et al.*, 1990). This fragment is termed a "co-peptide" which is immediately downstream of the signal peptide in the prepro-insulin related peptide of *L. migratoria*. The co-peptide is just upstream of the B-chain, which is followed by the C-peptide, and then the A-chain. Each peptide is separated by dibasic amino acid cleavage sites. In the mature insulin related peptide, the A- and B-chains are joined by two disulfide bonds, with an additional, internal disulfide bond in the A-chain. The C-peptide is not known to have a biological role in vertebrates, and the co-peptide might be presumed to have no activity. Synthesis of the *L. migratoria* co-peptide and bioassay revealed that it inhibits glycogen phosphorylase in the fat body, an effect expected of an insulin-like hormone. However, it has no effect on hemolymph lipid levels. Bombyxin, the first insulin related peptide discovered in insects, actually lowers storage carbohydrates in *Bombyx mori*, a paradoxical effect for a homolog of insulin (Satake *et al.*, 1997). The co-peptide certainly merits more detailed physiological study. Of some concern is the generality of these results: examination of the precursors of insulin related peptides in *B. mori*, *A. gambiae*, and *D. melanogaster* revealed that none of them contain the corresponding co-peptide; the B-chain in each begins immediately after the signal peptide.

In the horsefly *Tabanus atratus*, two peptides with AKH activity have been identified: Tabat-AKH and Tabat-HoTH (Jaffe *et al.*, 1989) (**Figure 1**). While Tabat-HoTH, a decapeptide, was claimed to have hypotrehalosemic activity (that expected for an insulin-like peptide rather than a member of the AKH/HrTH family), examination of **Figure 5b** in Jaffe *et al.* (1989) reveals that the curves showing dose-dependent differences between hemolymph sugars in control versus Tabat-HoTH treated larvae are but a trend and have overlapping standard deviations; no statistical tests were applied. Thus, the claims for hypotrehalosemic activity are unsupported by the published data.

3.10.3. Hormonal Control of Water and Electrolyte Homeostasis

Insects are small and hence have a high surface area to volume ratio, making them vulnerable to desiccation. Nevertheless, insects have evolved to be the most populous and diverse of all terrestrial animals. Insects have cuticles covered with water-impervious hydrocarbons to minimize water loss, and employ a variety of other behavioral, morphological, and physiological adaptations to keep water loss to a minimum, particularly in species that occupy very dry habitats. To maintain fluid homeostasis, water gained from the diet, metabolism and, in some species, from the atmosphere, must equal water lost by evaporation, respiration, and excretion. Evaporative and respiratory losses vary with environmental factors and the state of hydration, but the major site of regulation is the excretory system, and water loss via this route can change dramatically depending on the physiological status of the insect. Excretory water loss is determined by the rate at which fluid enters the hindgut from the midgut and Malpighian tubules (MT), and the rate of reabsorption therein. Fluid and ion homeostasis are under endocrine and possibly neural control, which allows the insect to regulate hemolymph volume and composition while permitting nitrogenous waste, toxic substances, and excess ions and/or water to be voided. The

endocrine factors affecting the regulation are referred to as diuretic hormones (DHs) and antidiuretic hormones (ADHs) although this may not precisely describe their actions. Generally, DHs stimulate primary urine secretion by MTs, whereas ADHs increase fluid reabsorption from the hindgut, but there are exceptions to this.

3.10.3.1. Molecular Basis for Urine Excretion

Urine excretion in vertebrates is primarily driven by blood pressure, but there is a complex interplay between a number of hormones in the control of fluid and ion homeostasis. Aldosterone and vasopressin (antidiuretic hormone) are largely responsible for maintaining electrolyte and water balance via reabsorption, while atrial natriuretic factor and angiotensin II primarily control blood volume (Beyenbach, 1993). In contrast, insects have low pressure circulatory systems and primary urine isosmotic to the hemolymph is secreted by the MT. Diuresis must therefore be driven by active ion transport, not by blood pressure. Diuretic hormones increase MT secretion by stimulating ion transport, whereas antidiuretic hormones either reduce MT secretion or stimulate fluid and vital solute reabsorption in the hindgut (Phillips, 1983) (**Figure 3**). A large literature exists on diuresis and its regulation in insects; early physiological studies have been reviewed comprehensively (Phillips, 1983; Spring, 1990). However, most early physiological studies on hormonal control of fluid homeostasis in insects utilized crude extracts of insect neuroendocrine tissues to affect target organs. It is now known that such studies dealt with a mixture of different active factors, so that unraveling mode of action of any single factor was impossible. A fundamental understanding of the control of fluid homeostasis requires that the controlling factors be identified, synthesized, and tested for their effects. Only availability of synthetic factors can allow a detailed

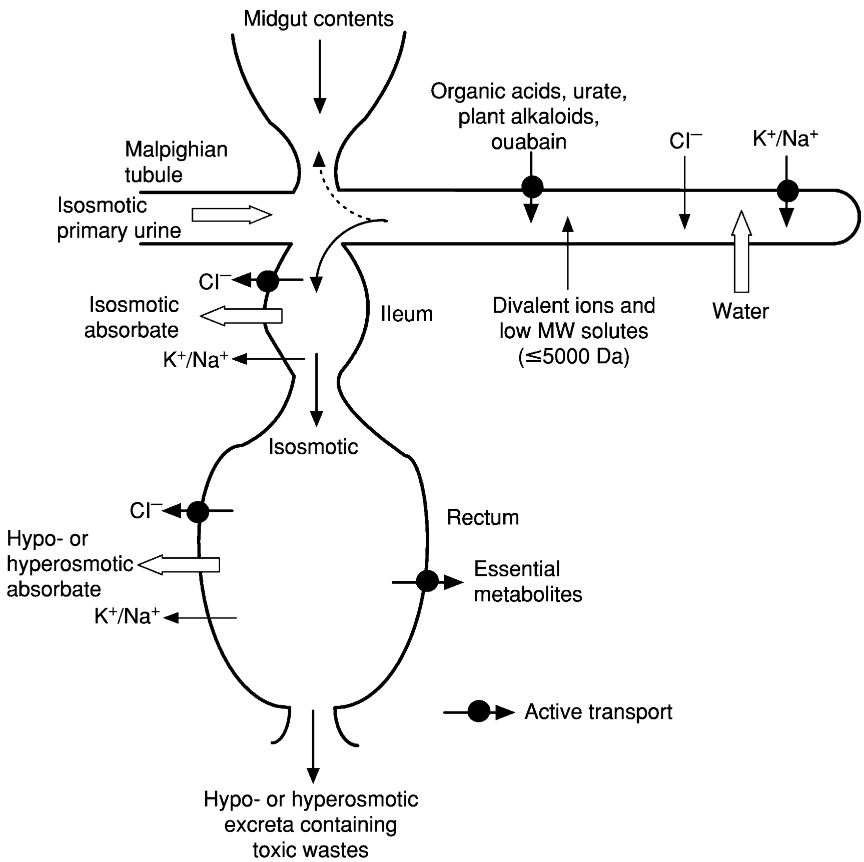

Figure 3 A generalized scheme of the classic view of the excretory process in insects. Malpighian tubule secretion is driven by the active transport of KCl and/or NaCl into the lumen, which draws water by osmosis. Other ions and metabolites enter the lumen by passive or active transporters. The primary urine enters the gut in most species at the midgut–hindgut junction and generally is directed posteriorly into the ileum and rectum where it is modified by isosmotic fluid reabsorption. The fluid entering the ileum and rectum is extensively modified by reabsorption of essential metabolites and fluid, which may be hypo- or hyperosmotic to the luminal contents. The driving force for ion transport is an apical electrogenic Cl^- pump, with cations entering passively, in contrast to the Malpighian tubules. Toxic wastes are retained in the hindgut lumen and are voided in the excreta, which can be strongly hypo- or hyperosmotic to hemolymph. (Modified with permission from Coast, G.M., Orchard, I., Phillips, J.E., Schooley, D.A., **2002a**. Insect diuretic and antidiuretic hormones. *Adv. Insect Physiol. 29*, 279–409.)

molecular understanding of the actions of factors controlling excretion and their physiological interplay, and whether prime control is due to diuresis or antidiuresis. There have been a number of reviews of the hormonal control of MT, and of hindgut function, focusing on identified hormones (Audsley *et al.*, 1994; Phillips and Audsley, 1995; Coast, 1996, 1998; Phillips *et al.*, 1998a; O'Donnell and Spring, 2000), and an extremely comprehensive review of both MT and hindgut function was published recently (Coast *et al.*, 2002b). The thrust of this review is to focus on advances in excretory physiology that concentrate on the effects of pure, defined factors.

An understanding of the molecular basis of basal urine production in the Insecta has emerged only during the last 15 years, and has been reviewed by Nicolson (1993) and Beyenbach (1995, 2003). Ion transport leading to basal secretion of urine by the MT is driven by an apical vacuolar-type H^+-ATPase (V-ATPase), in parallel with an apical cation/H^+ antiporter (Grinstein and Wieczorek, 1994). In a yellow fever mosquito, *Aedes aegypti*, MT, this transporter is believed to be a 1 cation:1 H^+ antiporter (Beyenbach, 2001), while in *M. sexta* midgut it is believed to be a 1 cation:2 H^+ antiporter (Azuma *et al.*, 1995). The activity of the V-ATPase is stimulated by treatment of tubules with cAMP or peptides elevating cAMP, and cGMP also stimulates its activity in *D. melanogaster* (O'Donnell *et al.*, 1996). The precise mechanism of stimulation is unknown; there is no evidence for phosphorylation of the V-ATPase, which lacks consensus sites for protein kinase A phosphorylation (Wieczorek *et al.*, 2000). A body of evidence suggests that activation of the *M. sexta* protein is related to association of the V_1 and V_0 subunits via a redox process (Grüber *et al.*, 2001); formation of a disulfide bond between Cys254 and Cys532 of the catalytic A protein of the yeast V_1 unit leads to reversible inactivation of the V-ATPase (Forgac, 2000), apparently via dissociation of the knob-like V_1 unit from the stalk-like V_0 unit.

The V-ATPase generates an electrochemical gradient favoring the entry of protons from the lumen in exchange for K^+ and/or Na^+ (Bertram *et al.*, 1991; Maddrell and O'Donnell, 1992; Weltens *et al.*, 1992) (**Figure 4**). The alkali cation-H^+ antiports of the hematophagous insect *R. prolixus* have a

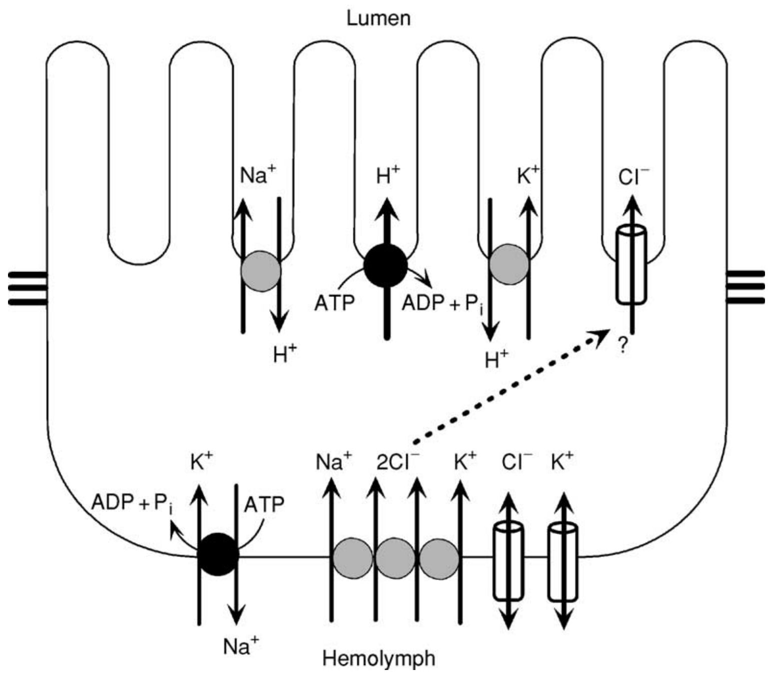

Figure 4 A generalized model for ion transport by Malpighian tubule principal cells. Active cation transport is energized by an apical (luminal) membrane H^+ pump (V-ATPase), which generates a gradient for protons to return to the cell via parallel K^+/H^+ and Na^+/H^+ antiports. Where there is a favorable electrochemical gradient, cations may enter principal cells by passive diffusion through ion channels in the basolateral membrane (notably K^+, but also Na^+ in *Aedes aegypti*). Other routes for cation uptake include primary (Na^+–K^+–ATPase) and secondary (Na^+–K^+–2Cl^- and K^+–Cl^- cotransport) active transport. Na^+ entry may also be coupled to the transport of organic solutes (not shown). Cl^- that enters the cells via cation-Cl^- cotransporters probably exits through channels in the apical membrane. Arrows with circles indicate primary (black circles) or secondary (gray circles) active transport, while arrows through cylinders represent membrane ion channels. (Modified with permission from Coast, G.M., Orchard, I., Phillips, J.E., Schooley, D.A., **2002a**. Insect diuretic and antidiuretic hormones. *Adv. Insect Physiol. 29*, 279–409.)

preference for Na^+ over K^+ (Maddrell, 1978; Maddrell *et al*., 1993b), whereas there appears to be no such preference in the house cricket, *A. domesticus* (Coast *et al*., 1991). Alkali cations enter principal cells through ion channels in the basolateral membrane, if the electrochemical gradient permits, or by secondary (e.g., cation/Cl^- cotransport) transport. The basolateral primary (Na^+–K^+–ATPase) active transporter has long been proposed to be important in MT transport processes, yet its known stoichiometry in vertebrate systems (3 Na^+ exported per 2 K^+ imported) is one opposing the observed direction of cation transport in MT. In fact, serotonin has been reported to inhibit the activity of the Na^+–K^+–ATPase in MT of *Rhodnius prolixus*, with this inhibition claimed to be responsible for some of the diuretic activity of this amine (Grieco and Lopes, 1997). However, indirect evidence suggests it may not play a significant role in *R. prolixus*, because ouabain, a potent inhibitor of this transporter, has no effect on fluid secretion (Ianowski *et al*., 2002). The Na^+–K^+–ATPase does not appear to be of functional importance in MT of *A. aegypti* (Weng *et al*., 2003) or in *M. sexta* (E. Chidembo and D.A. Schooley, unpublished data), as judged by a lack of vanadate or ouabain sensitivity of ATP hydrolase activity. In contrast, in *T. molitor* the Na^+–K^+–ATPase seems to play an important role in maintenance of cell K^+ concentration, and ouabain is an irreversible inhibitor of MT fluid secretion (Wiehart *et al*., 2003). These species differences may be explained by the nature of cations secreted in primary urine; in the cryptonephric tubules of *T. molitor*, activities of K^+ exceeding $3\,mol\,l^{-1}$ have been reported (O'Donnell and Machin, 1991), whereas *A. aegypti* secrete large amounts of Na^+ (Hegarty *et al*., 1991). Species or order differences in the relative activity of the Na^+–K^+–ATPase may also underlie the high levels of hemolymph K^+ versus Na^+ in many Lepidoptera, Coleoptera, and Hymenoptera (see Sutcliffe, 1963 and Section 3.10.3.12.1): a low activity of Na^+–K^+–ATPase in epithelial tissues would remove the driving force for keeping blood K^+ levels low versus Na^+ in hemolymph of most insect orders.

In general, the electrochemical gradient over the epithelium favors Cl^- diffusion into the lumen through a shunt pathway. The Cl^--selective shunt described by Pannabecker *et al*. (1993) in MT of *A. aegypti* does not appear to be in the principal cells, and is either paracellular or through a second cell type, the stellate cells, which form thin (3–5 μm deep) windows between the hemolymph and tubule lumen. Not all species have stellate cells; recently, they have been shown to have a different embryonic origin than principal cells (Denholm *et al*., 2003). Agents elevating intracellular Ca^{2+} increase Cl^- conductance, but do not stimulate the V-ATPase.

3.10.3.2. A Multiplicity of Peptides Regulate Diuresis and Antidiuresis in Insects

A number of "model species" have been adopted by different investigators for studying diuresis and antidiuresis. The classic work of Ramsay (1954) was performed with a stick insect, *Carausius morosus*. A great deal of pioneering work on diuresis and its control has been done with the hematophagous hemipteran *R. prolixus* (Maddrell, 1963) and *D. melanogaster* has been proposed as a useful model for studying diuresis in insects (Dow *et al*., 1998; MacPherson *et al*., 2001). The Beyenbach group has studied ion transport mechanisms in *A. aegypti* for decades (Beyenbach, 2003). Locusts have been the preferred model for studying the role of the hindgut in fluid reabsorption, largely through the work of the Phillips group (Phillips and Audsley, 1995).

The first hint that more than two different classes of peptides acted on MT was supplied by the Beyenbach group's studies of regulation of *A. aegypti* tubules by nervous system extracts separated on HPLC (Petzel *et al*., 1985). The first undisputed identification of an insect DH was the identification from *M. sexta* of a 41 amino acid peptide with high sequence similarity to the sauvagine/urotensin/urocortin/corticotropin releasing factor (CRF) family (Kataoka *et al*., 1989b). To date, 13 "CRF-like" DH structures have been identified by isolation and Edman degradation; four were identified by BLAST searches of the *D. melanogaster*, *A. gambiae*, and *B. mori* genomes (**Figure 5**). Somewhat later, the leucokinins (myotropic peptides originally isolated based on their ability to cause contractions of the cockroach hindgut) were also shown to have potent diuretic effects (Hayes *et al*., 1989). Currently, 33 different myokinin sequences are known from nine species of insects. In the last few years, it has become evident that a "cocktail" of neuropeptides are implicated in the regulation of MT secretion (Coast *et al*., 2002a; Skaer *et al*., 2002). The majority of these peptides have diuretic activity, stimulating fluid secretion. Others have antidiuretic activity and reduce the rate of secretion. From the mid-90s onwards, peptides belonging to four families in addition to the CRF-like DHs and myokinins have been shown to influence tubule secretion: the calcitonin-like (CT-like) DHs, CAP_{2b}-like, tachykinin

related peptides, and two antidiuretic factors, ADFa and ADFb. The greatest amount of research has been carried out on the first two families discovered, i.e., the CRF-like and myokinin families; these appear to be ubiquitous among insects, although there is considerable interspecific variation in activity. For example, the CRF-like DH of *A. domesticus* stimulates maximal secretion, and is about threefold more active than the native myokinins (Coast *et al.*, 1992). Alternatively, in *D. melanogaster* and in *M. domestica* (Holman *et al.*, 1999), the CRF-like DHs have poor activity compared with the native kinin. The situation is even more extreme in *R. prolixus*, where CRF-like peptides can elicit maximal secretion and myokinins appear to be inactive (Te Brugge *et al.*, 2002).

CT-like, CAP_{2b}-like, and tachykinin related peptides may also be of widespread occurrence in insects, but have been investigated less extensively than the CRF-like DHs and myokinins. Indeed, to date, CT-like peptides have only been identified in three species, *Diploptera punctata*, *D. melanogaster*, and *Formica polyctena* (a partial sequence), and three in the genomes of *A. gambiae*, *B. mori*, and *Apis mellifera*, but these represent very diverse orders (Dictyoptera, Diptera, Lepidoptera and Hymenoptera, respectively). There is immunological evidence for the existence of these factors in six other insect species representing the Orthoptera, Coleoptera, Hemiptera, and Lepidoptera (see Section 3.10.3.5). Even less is known of the antidiuretic factors controlling MT secretion since these have only been described in *T. molitor*. Intriguingly, peptides that have diuretic activity in one species have been shown to have antidiuretic activity in another. Manse-CAP_{2b} is a diuretic in Diptera (*D. melanogaster* and *M. domestica*), but an antidiuretic in *R. prolixus* and *T. molitor*. CAP_{2b} has no effect on secretion by MT of *M. sexta* at 1 μmol l^{-1} (Skaer *et al.*, 2002), the latter organism being the host from which it was identified. Tenmo-ADFb is antidiuretic in *T. molitor* and *A. aegypti*, but a diuretic in *A. domesticus* (G.M. Coast, unpublished data). Even when comparing quite similar species, peptide activity can vary considerably, as for CAP_{2b} in *D. melanogaster* and *M. domestica*. In *D. melanogaster*, CAP_{2b} acts on principal cells to activate a calcium-calmodulin dependent NO synthase, and the rise in NO levels increases cGMP production by a soluble guanylate cyclase. Diuresis results from the cGMP dependent stimulation of an apical membrane V-type ATPase that powers fluid secretion (Davies *et al.*, 1995). Conversely, CAP_{2b} has no effect on cGMP levels in *M. domestica* tubules or on the activity of the V-type ATPase. Instead, diuresis results from the opening of a passive chloride shunt pathway, which has previously been attributed to myokinin stimulation (C.S. Garside and G.M. Coast, unpublished data).

3.10.3.3. CRF-Like DH

The first insect DH identified was Manse-DH, a 41 residue peptide isolated from 10 000 heads of pharate adult *M. sexta* using an *in vivo* assay (Kataoka *et al.*, 1989b). This assay for monitoring the isolation utilized beheaded, newly eclosed adults of *Pieris rapae*, similar to a technique described by Nicolson for *Pieris brassicae* (Nicolson, 1976). Manse-DH has 41% sequence identity with sauvagine, a peptide isolated from skin of the frog *Phyllomedusa sauvagei* (Montecucchi and Henschen, 1981) and believed for some time to be the amphibian form of CRF. The direct sequence identity with CRF is somewhat lower. Subsequently a smaller peptide, Manse-DPII, was isolated from dissected neuroendocrine cells of brains of *M. sexta*. Again, an *in vivo* bioassay was used to monitor the isolation using adults of *M. sexta*. Due to the extremely small amount of tissue extracted in this "surgical purification" method, the peptide was obtained in a pure state after a single step of reversed-phase liquid chromatography (RPLC) (Blackburn *et al.*, 1991). However, the amount of peptide isolated was so small that only a partial sequence was determined by Edman degradation; complete structure proof required mass spectral sequencing. As aligned in **Figure 5**, Manse-DPII has only nine residues identical with those in Manse-DH. Also in 1991, CRF-like DHs were isolated from *A. domesticus* and *L. migratoria*; the former was isolated based on its ability to increase levels of cAMP in MT of *A. domesticus* maintained *in vitro* (Kay *et al.*, 1991a). This 46 amino acid peptide, Achdo-DP, is clearly a third member of the "CRF-like" DH. Two publications reported the sequence of the same DH from *L. migratoria* within a few weeks of each other; both utilized purifications by multiple steps of RPLC. Lehmberg *et al.* required only three RPLC purification steps to isolate this peptide to homogeneity from 4000 dissected locust brains using a direct enzyme-linked immunosorbent assay (ELISA) with antibodies raised against Manse-DH (Lehmberg *et al.*, 1991). Kay and colleagues utilized whole heads of *L. migratoria* to isolate Locmi-DH, monitoring the four-step RPLC isolation procedure with the *in vitro* assay for cAMP production with MTs of the locust (Kay *et al.*, 1991b).

In 1992 Kay *et al.* identified from *P. americana* a 46 residue DH, which differs from Locmi-DH at 13 residues, and from Achdo-DP at 18 residues. MT of

L. migratoria were used to monitor the isolation of this peptide, because of extreme variability between cockroach tubules (G.M. Coast, unpublished data). Much later, Furuya *et al.* (2000b) isolated a 46 residue DH from the Pacific beetle roach, *Diploptera punctata*, which still differs from Peram-DH at nine residues. Another 46 residue DH from *Zootermopsis nevadensis* (Baldwin *et al.*, 2001), a dampwood termite, differs from Peram-DH at only three residues, and thus is ranked phylogenetically between the two cockroach DHs by the sequence alignment program utilized, Clustal W version 1.8 (**Figure 5**). It is curious that these 46 residue DHs, while being relatively more related to one another than the other CRF-like DH, still vary highly in sequence. An interesting observation with *Z. nevadensis* is that this species contains another DH that elevates cAMP in tubules of *M. sexta*, the species used to assay the isolation of Zoone-DH. This second factor is more basic, but less hydrophobic, than Zoone-DH; two attempts to isolate it were unsuccessful, because of its lability in the acidic solvents used for extraction (Baldwin *et al.*, 2001).

The first, and to date only, case of two species having an identical CRF-like DH sequence was the identification of Musdo-DP from *M. domestica* and *Stomoxys calcitrans* (Clottens *et al.*, 1994). The assay to monitor the purification scheme was based on elevation of cAMP in MT of *M. sexta* maintained *in vitro*. This 44 amino acid peptide was accompanied by another, more hydrophobic active factor in *S. calcitrans*. The existence of this unknown factor has been reported (see Schooley, 1994), but, unfortunately, no details of its properties were ever published. Audsley *et al.* (1995) advocated the use of *M. sexta* MT for a general heterologous bioassay for isolation of DH from other species, because these MT proved to cross-react more promiscuously with all CRF-like DH tested than MT of *L. migratoria* or *A. domesticus*. A DH was isolated from the salt water mosquito, *Culex salinarius*, the isolation of which has never been reported, although its sequence and biological properties have been published (Clark *et al.*, 1998a). This 42 residue peptide differs from the Musdo-DH sequence at nine positions. Two more dipteran CRF-like DHs have been identified from the genome of *D. melanogaster* (Cabrero *et al.*, 2002) and *A. gambiae*. Drome-DH_{44} differs from Musdo-DH at only one residue: the substitution of a Ser at position 31 for a Thr in Musdo-DH. In contrast, Anoga-DH_{44} differs from Musdo-DH by seven residues. All dipteran DHs isolated to date are two residues (in one case four residues) shorter than the 46-mers isolated from the Orthoptera, Dictyoptera, and a single isopteran.

Figure 5 The CRF-like DHs and the CRF superfamily of peptides – the blue colored residues emphasize the similarities among the CRF-like DHs. Sauvagine, urotensin I, and urocortin 1 are paralogs of CRF. The CRF-like DHs are shown using the Swiss Prot species abbreviations (defined in the text except for Bommo (*Bombyx mori*, whose genome sequence appeared while the article was in press)); wsUrot I, *Catostomus commersoni* urotensin I; Xenla, *Xenopus laevis*. The four identical CRFs are from human (h), rat (r), goat (c), and horse (e). Two residues (shown in red) are conserved in the lepidopteran DHs and the CRF superfamily. The unique C-termini of the *Tenebrio molitor* DH are shown in green.

An unusual CRF-like DH was identified in *T. molitor* (Furuya *et al*., 1995); its isolation was monitored by the elevation of cAMP from MT of this species maintained *in vitro*. This 37 residue DH, Tenmo-DH_{37}, was isolated from 8400 pupal heads of *T. molitor*, and was accompanied by a less abundant, more hydrophobic factor isolated in insufficient quantity to sequence. Only later was the structure of this second factor reported, after extraction of an additional 20 000 heads, combined with the active fractions from identification of Tenmo-DH_{37}. The peptide isolated, Tenmo-DH_{47}, is the largest CRF-like DH identified to date (Furuya *et al*., 1998) at 47 residues, and is much less abundant than its small congener. Structurally, both peptides differ from all other CRF-like DH in having their C-terminal residue existing in the free carboxylate form rather than being amidated. In addition, Tenmo-DH_{37} has a one-residue "extension" of its sequence: all sequences from organisms other than *T. molitor* have a C-terminal Ile-amide or Val-amide, whereas Tenmo-DH_{37} has a Leu-Asn-OH C-terminus, and Tenmo-DH_{47} has a Leu-OH, lacking the Asn extension of its smaller congener. A physiological consequence of this structural difference is that Tenmo-DH_{37} is without any detectable biological activity on MT of *M. sexta*: its activity is $\leq 10^4$ lower than Manse-DH in this assay. This is consistent with data on the free acid form of Manse-DH which is about 1000-fold less active than the natural, amidated form in the *P. rapae* assay (Kataoka *et al*., 1989b). The more abundant, smaller Tenmo-DH_{37} was found to be about 600-fold more potent than the larger peptide in an *in vitro* assay measuring cAMP production with adult MT (Furuya *et al*., 1998), and about 200-fold more potent in a Ramsay fluid secretion assay with larval MT (Wiehart *et al*., 2002). However, Manse-DH is only 17-fold less active than Tenmo-DH_{37} in the cAMP assay with adult MT (Furuya *et al*., 1995). The two latter DHs have only 15 residues in common in the alignment in **Figure 5**, with Tenmo-DH_{37} being more similar to Manse-DPII, and Tenmo-DH_{47} being more similar to the "longer" CRF-like DH.

Two DHs were isolated from the white-lined Sphinx, *Hyles lineata*, a close relative of *M. sexta* (Furuya *et al*., 2000a). The larger of these, Hylli-DH_{41}, differs from Manse-DH only at residue 27, which is Gln rather than His (Manse-DH). Similarly, the shorter DH, Hylli-DH_{30}, differs from Manse-DPII only at residue 9, by a conservative substitution (Glu in the *H. lineata* peptide for Asp in Manse-DPII). Thus, the sequences of two DHs from each of three species are currently known, and it is apparent that these form a group of paralogous sequences. It is fascinating to contrast the CRF-like DH with the CRF superfamily of peptides in vertebrates. In 1991, two CRF sequences were identified by cDNA cloning in the white sucker *Catostomus commersoni*. The sucker CRFs differ from the sequences of human, horse, rat, and dog CRF (all identical) at only one and two residues (Morley *et al*., 1991), yet are only 54% identical with urotensin, the fish equivalent of sauvagine. The following year, a similar situation was discovered with *Xenopus laevis*, which has two forms of CRF differing from the human sequence at only 2 and 3 residues (Stenzel-Poore *et al*., 1992). Consequently a sauvagine (or urotensin)-like peptide was sought and found in rat brain: urocortin 1, a vertebrate ortholog of urotensin and sauvagine (Vaughan *et al*., 1995). Thus, the CRF superfamily in vertebrates consists of two paralogous subfamilies of sequences, a situation mirrored in the CRF-like DH, although the sequences are very highly conserved in vertebrates in contrast with those known from insects.

Examination of the sequences of the 15 known CRF-like DHs (**Figure 5**) reveals only four amino acids that are completely conserved in this family. Two of these are a Ser and a Leu, but they are separated by seven amino acids. The others are an Asn and a Leu in the C-terminal domain, separated by three amino acids. The Leu is separated from the C-terminal residue by two amino acids (three in Tenmo-DH_{37}). Consequently, the prospects for using degenerate probes to attempt to isolate additional new members of this family from cDNA or mRNA are very poor. Curiously, in the CRF superfamily of peptides, again only four residues are completely conserved; one is the Ser also conserved in the CRF-like DH, and another the Asn near the C-terminus. The other two totally conserved residues in the CRF superfamily differ from those in the CRF-like DH. Despite the exceptional sequence conservation of the various forms of CRF, the paralogs sauvagine, urotensin, and urocortins diverge considerably (Hauger *et al*., 2003).

Aside from the genome sequences for Drome-DH_{44}, Boomo-DH_{41}, Bommo-DH_{34}, and Anoga-DH_{44}, to date only one gene sequence encoding a CRF-like DH has been determined by cloning; that is for Manse-DH (Digan *et al*., 1992). The prepropeptide has a 19 residue signal peptide for cellular secretion, followed by a 61 residue propeptide terminating in Lys-Arg (the cleavage site for a Kex-2 like processing enzyme), then the 41 residues of Manse-DH, followed by a Gly-Lys-Arg plus 15 additional amino acids of the propeptide. The

Lys-Arg processing site results in a C-terminal Gly, which provides the amidation on the C-terminal Ile following action of peptidylglycine amidating monooxygenase (Prigge *et al*., 2000) on the Gly residue.

Another aspect of the sequence alignment is worth noting. A Pro residue is situated either exactly between the totally conserved Ser and Leu residues in the N-terminal domain, or one residue closer to the Ser in two of the three "short" CRF-like DHs. The residue just upstream of this Pro is Asn in 11 of the 15 CRF-like DH, Ala in two, and Leu in two. The Asp-Pro bond, not observed in any DH isolated to date, is exceptionally labile to acid on standing in solution, and the Asn codon requires but a single base change to give Asp. The inability to isolate the second CRF-like DH from *Z. nevadensis* was probably due to the presence of an Asp-Pro bond (Baldwin *et al*., 2001); multiple attempts to isolate a CRF-like factor from heads of *A. mellifera*, assayed by its strong stimulation of MT of *M. sexta*, were totally unsuccessful because the activity would disappear after only a few steps (E. Lehmberg and D.A. Schooley, unpublished data).

There are very few studies on structure–activity relationships with the CRF-related DHs because of their size and difficulty of solid-phase chemical synthesis. Studies with Manse-DH and Achdo-DP show that a region near the N-terminus is important for receptor activation while the remaining portion of the peptide is required for receptor binding. An analog Manse-DH(13–41), truncated by 12 residues at the N-terminus, binds Manse-DHR expressed in Sf9 cells with high affinity (IC_{50} ~2.8 nmol l^{-1} versus 0.16 nmol l^{-1} for the intact peptide) but does not stimulate cAMP production, whereas Manse-DH (3–41) has high receptor binding affinity and is a potent stimulant of adenylate cyclase (Reagan, 1995a). Manse-DH(21–41) and Manse-DH(26–41) have binding affinities reduced 100-fold and 1000-fold, respectively, while Manse-DH(31–41) has no binding activity at 1 μmol l^{-1} (Reagan *et al*., 1993). Deletion of the first four residues from Manse-DH decreases activity, while deletion of the next residue essentially abolishes it (P. Dey and D.A. Schooley, unpublished data). Taken together with the results of Reagan (1995a), this suggests that the receptor activating domain of Manse-DH lies very close to the N-terminus. Studies with N-terminal truncated analogs of Achdo-DP in a cricket tubule fluid secretion assay confirm the importance of the N-terminus for receptor activation (Coast *et al*., 1994). The activities of Achdo-DP(6–46) and Achdo-DP(7–46) are essentially indistinguishable from intact Achdo-DP, but the activity of Achdo-DP(11–46) is reduced by 60% and Achdo-DP(23–46) is inactive. These data could suggest that the domain necessary for receptor activation is farther from the N-terminus in Achdo-DP than in Manse-DH. However, results for peptides with low activity in a series of deletion peptides must be interpreted with caution; such peptides are made by removing peptide synthesis resin at various stages of the synthesis, which proceeds from the C- to the N-terminus. Usually all synthetic deletion peptides are purified using the same preparative RPLC column; traces of biological activity from a full-length, or nearly so, peptide will bleed out of a column essentially permanently (D.A. Schooley, unpublished data). Thus, the shortest peptides must be purified first on a new column. Intact Met residues may be important for activity; one of the Met residues (at position 1, 3, or 13) in Locmi-DH can become oxidized, with a resultant loss of activity (I. Kay and G.M. Coast, unpublished data). This may explain why $[Nle^{2,11}]$-Manse-DH (with Nle replacing Met^2 and Met^{11}) maximally stimulates cricket tubule secretion, whereas Manse-DH gives only a 60% response (Coast *et al*., 1992). In addition, Locmi-DH(1–23) and Locmi-DH(24–46) are inactive whether tested separately or together (Nittoli *et al*., 1999) (G.M. Coast, unpublished data); thus, the binding and activation domains must be joined together to have a biologically active peptide.

Manse-DH with a free C-terminus (acid) stimulates cAMP production by adult *M. sexta* MT (Audsley *et al*., 1995) and posteclosion diuresis in decapitated newly emerged *P. rapae* (Kataoka *et al*., 1989b), but in both assays it was 1000-fold less potent than Manse-DH. Reagan *et al*. (1993) were unable to detect any binding of this ligand to the Manse-DHR, which they attributed to rapid degradation of the nonblocked peptide (presumably by carboxylpeptidases) in the receptor binding assay.

3.10.3.4. Diuretic and Myotropic Peptides: the Kinins

Insect kinins (originally called myokinins) were isolated from whole head extracts of the Madeira cockroach, *Leucophaea maderae* (leucokinins; Leuma-Ks) (Holman *et al*., 1986a, 1986b, 1987a, 1987b) based on their potent myotropic activity in a cockroach (*L. maderae*) hindgut assay (Holman *et al*., 1991). The eight leucokinins differ in myotropic potency. They were later found to be potent stimulants of fluid secretion in *A. aegypti*, also causing a depolarization of the transepithelial potential (Hayes *et al*., 1989). Soon thereafter, five kinins (achetakinins; Achdo-Ks) were isolated from *A. domesticus* using the *L. maderae* hindgut assay; they were shown to also possess high diuretic activity on MT

of *A. domesticus* (Coast *et al.*, 1990). Similarly, locustakinin was isolated from 9000 brain–corpora cardiaca–corpora allata–subesophageal complexes of *L. migratoria* using the *L. maderae* hindgut assay (Schoofs *et al.*, 1992). It is curious that only a single kinin, locustakinin (Locmi-K), was isolated from this species, whereas all other orthopterans and dictyopterans studied to date have 5–8 kinins. Using hindgut of *P. americana*, eight kinins were isolated from 800 corpora cardiaca–corpora allata of this species (Predel *et al.*, 1997), five of which are unique sequences, while three occur in other species: Locmi-K, Leuma-K-7, and Leuma-K-8. Availability of endogenous kinins is crucial to understanding their role in any species. For example, muscakinin is about 10^6 more potent in *M. domestica* (Holman *et al.*, 1999) than leucokinin I.

The first kinins to be identified from a holometabolous species were those from *A. aegypti*, which were isolated using an ELISA rather than a functional assay (Veenstra, 1994). While these were termed "*Aedes* leucokinins 1–3," this nomenclature suggests they may be the same sequence as those from *L. maderae*, but they are in fact unique. Here the Swiss-Prot-NCBI five-letter standards for species abbreviation, Aedae-K-1, Aedae-K-2, and Aedae-K-3, as previously recommended is used (Coast *et al.*, 2002a). Later, the sequence of the single cDNA encoding these kinins was determined, and their biological properties determined (Veenstra *et al.*, 1997). While all three Aedae-K peptides are capable of depolarizing the mosquito MT at doses between 0.1 and 1 $nmol\,l^{-1}$, only Aedae-K-3 gave good stimulation of fluid secretion, with an EC_{50} near 10 $nmol\,l^{-1}$; Aedae-K-3 was appreciably less active and Aedae-K-2 was without effect on fluid secretion at 1 $\mu mol\,l^{-1}$. Three kinins were isolated from wild-collected salt marsh mosquitos, 94% of them *C. salinarius*, and the first kinin was christened "culekinin depolarizing peptide" (Hayes *et al.*, 1994). They were isolated using the *L. maderae* hindgut assay, as well as an electrophysiological assay with tubules of *A. aegypti*. The sequence of only the heptamer Culsa-K-1 was published (Hayes *et al.*, 1994). Some years later, the biological properties of Culsa-K-2 and Culsa-K-3, along with the sequences, were published by other workers (Cady and Hagedorn, 1999a, 1999b), but details of their isolation and identification remain unpublished. These peptides stimulate inositol trisphosphate (IP_3) concentrations in MT of *A. aegypti*, with no effect on cAMP levels (Cady and Hagedorn, 1999b). Further, they stimulate *in vivo* urine production in adult female mosquitos (Cady and Hagedorn, 1999a). Using the sequences of the Aedae-K as a BLAST query of the *A. gambiae* genome (Holt *et al.*, 2002), a single gene encoding three different kinins of 15, 10, and 21 residues was located: Anoga-K-1, -K-2, and -K-3. These peptides occur in the gene in the size order shown; the first and second are separated only by the amino acid residues Gly-Lys-Arg, as are the second and third (residues necessary for cleavage from the propeptide and formation of the amidated C-terminus). There are no reports of their synthesis and biological properties as yet.

Holman *et al.* (1999) isolated a 15 residue kinin from another fly species, *M. domestica*, using an ELISA with an antibody raised against Leuma-K-1. Musdo-K strongly stimulates fluid secretion in *M. domestica* MT, whereas the hexapeptide Achdo-K-5, identical with the six C-terminal residues of Musdo-K, is 1000-fold less potent in this assay. Thus, the longer sequence is crucial for full activity in *M. domestica*. Musdo-K also stimulates the housefly hindgut, possibly aiding in excretion. Later that year, Terhzaz *et al.* (1999) reported the isolation of a single 15 residue kinin from *D. melanogaster*, using a purification strategy based on that for the Aedae-K peptides. The sequence differs from Musdo-K at the second residue, a Thr in Musdo-K versus a Ser in Drome-K. A portion of the gene encoding a partial propeptide was determined from a BLAST search of sequenced bacterial artificial chromosomes of the then-incomplete *D. melanogaster* genome. Studies of the effects of Aedae-K on MT showed that it elevates intracellular Ca^{2+}, but not cAMP. A BLAST search of the now-complete genome of this species verifies that the *pp* gene encodes but a single kinin.

The isolation of kinins from a lepidopteran insect, the corn earworm *Helicoverpa zea*, is of interest because only the first step utilized a functional assay. Blackburn *et al.* (1995) used ~2000 abdominal ventral nerve cords (VNC) from adult moths as tissue source. Homogenized tissues were prepurified on a Sep-Pak C_{18}, and then fractionated on RPLC. Fractions were assayed using a Ramsay assay with MT of adult *M. sexta*. Three fractions with diuretic activity coincided with peaks having strong absorbance at 280 nm, which gave second derivative UV spectra characteristic of Trp, one of three amino acids totally conserved in the kinins. Subsequent purification steps were monitored based on the diagnostic UV spectral behavior of Trp, rather than by using a functional assay. The peak eluting first was purified to homogeneity in one more RPLC step, and sequenced by Edman degradation (Helze-K-III; see **Figure 6**). The other two peptides, present in

Figure 6 A multiple sequence alignment (Clustal W, V. 1.8) of the 33 known insect kinins from nine species. Boxed residues are identical. At the C-terminus, a five amino acid motif is highly conserved: FX_1X_2WGamide. X_1 is N, S, Y, or H in all known sequences. X_2 is usually S, but may be P or A. The first kinins were isolated from *Leucophaea maderae* (Leuma). For the definition of other species' abbreviations, see text. Note most of the dipteran kinins cluster towards the center of the alignment. There is immunocytochemical evidence for the presence of kinins in over 15 species of insects. Interested parties are referred to a recent, massively comprehensive review (Coast *et al.*, 2002a).

smaller quantity, required two additional steps for purification to homogeneity. The Trp residue could not be detected by Edman sequencing in these two kinins, which were additionally sequenced by tandem MS sequencing methods. The deduced sequences of all Helze-Ks were synthesized, and bioassayed on MT of *M. sexta*. No EC_{50} values were determined, only "threshold values": the lowest concentration at which a significant effect on fluid secretion can be measured. These were $\sim$7 pmol l^{-1} for Helze-K-I, 0.6 pmol l^{-1} for Helze-K-II, and 6 pmol l^{-1} for Helze-K-III. None of these peptides had activity *in vivo* in *H. zea*, but they do not appear to have been tested *in vitro* in *H. zea*, or *in vivo* in *M. sexta*, so no valid comparison can be drawn. While kinins have not yet been identified in *R. prolixus*, partially purified extracts from neuroendocrine tissue of this species, which contain kinin-like immunoreactivity, do not stimulate tubule secretion, but are active on the hindgut (Te Brugge *et al.*, 2002).

3.10.3.5. Calcitonin-Like DH

The first member of this family was identified together with the CRF-like Dippu-DH_{46} isolated from 4000 brains of *D. punctata* (Furuya *et al.*, 2000b). During the first step of RPLC purification of extracts, only one fraction (corresponding to Dippu-DH_{46}) stimulated cAMP production by MT of *M. sexta*, yet this fraction and a faster eluting fraction both elevated cAMP production by MT of *S. americana*. Because the *M. sexta* assay is easier, it was utilized to isolate Dippu-DH_{46}. Isolation to homogeneity of the second factor was accomplished using MT of *S. americana*. Upon sequence analysis, it was immediately apparent that this 31 residue peptide was not a member of the CRF-like DH. A BLAST search revealed similarities to certain proteins, but no highly significant resemblance to any bioactive peptides. Nevertheless, a manual search through the catalog of a commercial supplier of peptides (Peninsula Laboratories) for the unusual GP-NH_2 C-terminal sequence revealed an interesting similarity to

calcitonin; in fact, only the calcitonin family has a Pro-NH_2 at the C-terminus of all bioactive peptides listed in this catalog. In the alignment shown in **Figure 7**, only 6 of 31 residues of Dippu-DH_{31} are well conserved in the calcitonin family. However, chicken calcitonin is only 30-fold less potent in a fluid secretion assay than Dippu-DH_{31} using MT of *D. punctata* (Furuya *et al*., 2000b), suggesting this to be a genuine homology: one of the main actions of calcitonin is lowering blood Ca^{2+} by increasing Ca^{2+} excretion by the kidneys, in addition to increasing Ca^{2+} deposition in bone, which require active transport mechanisms. Interestingly, Dippu-DH_{31} and Dippu-DH_{46} have potent synergistic interaction in *D. punctata* (Furuya *et al*., 2000b). The actions of Dippu-DH_{31} in *L. migratoria* are more consistent with an elevation of intracellular Ca^{2+} in this species (Furuya *et al*., 2000b). These apparent differences in signaling are not surprising in light of the fact that a single, cloned calcitonin receptor has been shown to be capable of activating both the adenylate cyclase and phospholipase C signal transduction systems (Chabre *et al*., 1992; Force *et al*., 1992).

To date, the only other characterized CT-like DH is that cloned "*in silico*" from the genome of *D. melanogaster* (gene Dh31 CG13094); this peptide, Drome-DH_{31}, was synthesized and shown to be a potent diuretic in fruit fly tubules, and to act via adenylate cyclase (Coast *et al*., 2001). Another homolog of Dippu-DH_{31} exists in the genome of *A. gambiae* (BX038390) (Riehle *et al*., 2002), Anoga-DH_{31}, but its biological function has not yet been studied. Moreover, with the recent availability of preliminary genome sequence data for *B. mori* and *A. mellifera*, genes encoding CT-like homologs exist in these two species (Bommo-DH_{31} and Apime-DH_{31}). Using a direct ELISA with an affinity-purified Dippu-DH_{31} antibody, immunoreactivity was observed in head extracts of *M. sexta*, *T. molitor*, *R. prolixus*, *A. domesticus*, *Blaptica dubia*, and the Mormon cricket, *Anabrus simplex* (V.C. Lombardi, J.J. Hull, V. Te Brugge, and D.A. Schooley, unpublished data). At the time of writing, isolation of the *M. sexta* ortholog of Dippu-DH_{31} is imminent. Thus, it is likely that the CT-like DHs constitute another family of DHs of widespread occurrence within the Insecta. The partial sequence of a similar peptide isolated from the Belgian forest ant, *Formica polyctena*, was published in a Ph.D. thesis (Laenen, 1999). The isolation of the factor was monitored by observing its stimulation of MT writhing in *L. migratoria*: sequence analysis of this peptide was only possible out to 29 residues, but all are identical with the first 29 residues of Dippu-DH_{31} (see **Figure 7**). MS analysis revealed that the sequence was incomplete; the last two amino acids not detected must be different from those in Dippu-DH_{31} because the M_r is lower than that of the latter peptide (Laenen, 1999). Because the peptide lacked any diuretic activity on tubules of *F. polyctena*, from which it was isolated, it was not investigated further. Unfortunately, this discovery predated the publication of the sequence of Dippu-DH_{31}; the sequence identity might have spurred completion of the sequence of the ant peptide despite its lack of diuretic activity in the host species.

Figure 7 The known calcitonin-like DHs are shown using the Swiss Prot species abbreviation convention: Forpo, *Formica polyctena*; other species abbreviations are given in text. In this figure, red is conserved in the calcitonin family; blue is conserved in Dippu-DH_{31} and homologs. Very recently (while this article was in press), the *Bombyx mori* (Bommo) genome became available. Limited genome sequence data also became available for *Apis mellifera* (Apime).

3.10.3.6. CAP_{2b}/Periviscerokinins

Manse-CAP_{2b} was isolated from *M. sexta* as a cardioactive factor (Huesmann *et al*., 1995). Davies *et al*. (1995) found that it stimulates fluid secretion from MT of *D. melanogaster* by the unusual action (for a peptide hormone) of elevating production of nitric oxide, which in turn activates a soluble guanylate cyclase. This peptide was reported, based exclusively on the retention time of biological activity from *D. melanogaster* tissue extracts on RPLC, to be an endogenous peptide in *D. melanogaster*. However, a BLAST search of the *D. melanogaster* genome (Vanden Broeck, 2001) revealed the existence of three homologs of CAP_{2b} with 8, 10, and 12 amino acid residues, having 6, 7, and 5 amino acid identities, respectively, to Manse-CAP_{2b} (**Figure 8**). Garside and Coast (unpublished data) have studied the activity of Manse-CAP_{2b} and Drome-capa-2 on MT of houseflies; in this species they are diuretic but signal transduction is not via NO or cGMP, but appears to result from an increase in intracellular Ca^{2+}. Predel *et al*. (1995) isolated a myotropin from perisympathetic organs of the cockroach *P. americana* christened periviscerokinin, which

Figure 8 The *Manduca sexta* CAP_{2b} family of peptides. All are amidated at the C-terminus (indicated with lower case a), and two (Manse-CAP_{2b} and Anoga-CAP_{2b9} have pyroglutamic acid as the N-terminal residue (denoted by pQ, because Gln (Q) is the precursor of pGlu). At least one of the peptides with low sequence similarity in the C-terminal domain (FPRVa), Peram-PVK-1 (from *Periplaneta americana*), has no diuretic activity, suggesting that the conserved C-terminal motif is crucial for activity.

seemed to be a peptide unrelated to other families of peptides. However, subsequently, this group (Predel *et al.*, 1998) isolated a second peptide from this source, Peram-PVK-2, whose sequence was obviously related to not only Peram-PVK-1 but also to CAP_{2b}. The CAP_{2b} family now consists of 14 members, with the addition of three peptides from the cockroach *L. maderae* (Predel *et al.*, 2000), one from the locust (Predel and Gäde, 2002), and three from the genome of *A. gambiae* (Riehle *et al.*, 2002) (**Figure 8**). Recently, partial sequences for two new members of this family were identified using highly sensitive mass spectrometric assays (Clynen *et al.*, 2003b) on single perisympathetic organs from two fly species, *Neobelleria bullata* and *M. domestica*. These sequences are incomplete because of the inability of MS analysis to distinguish between Ile and Leu in peptides, and because of lack of certain crucial diagnostic ions and are therefore not given in **Figure 8**. It is novel that this approach to isolation and identification does not require a bioassay.

3.10.3.7. Arginine Vasopressin-Like Insect Diuretic Hormone

Proux *et al.* (1982) found that a factor in the subesophageal ganglia of *L. migratoria* stimulated *in vivo* clearance of injected amaranth from the hemolymph of locusts, an established assay for diuresis in this species (Mordue, 1969), and obtained evidence that this material was identical to a factor that cross-reacts with arginine vasopressin (AVP). This factor was isolated from 51 000 dissected subesophageal and thoracic ganglia using RPLC techniques with monitoring of fractions with a radioimmunoassay for AVP. In the first step of isolation two factors were separated, both of which were purified to homogeneity (Schooley *et al.*, 1987). Injection of the purified factors into *S. gregaria* revealed that only the less abundant, slower eluting factor (F2) caused amaranth excretion. The faster eluting F1 and slower eluting F2 were found to have identical amino acid compositions and identical primary sequences: Cys-Leu-Ile-Thr-Asn-Cys-Pro-Arg-Gly-NH_2. This peptide was synthesized in both the amidated and free acid forms, and after reduction and carboxymethylation was compared with the similarly modified forms of F1 and F2 prepared for sequence analysis. This comparison established that F1 was identical to the nonapeptide whose sequence is shown above. Analysis of both materials by size exclusion chromatography suggested that F2 was a dimer of F1. Two separate, difficult specific syntheses were performed to prepare pure F2 as parallel and antiparallel dimers (Proux *et al.*, 1987). The synthetic antiparallel dimer proved to have identical retention properties on RPLC with F2 (Proux *et al.*, 1987). Natural and synthetic F2 were shown to promote fluid secretion in an unusual fluid secretion assay in which a group of *L. migratoria* MT attached to the ampulla were removed, maintained in oxygenated saline, and the high combined flow of all tubules monitored (Proux *et al.*, 1988).

Later, this work was called into question by Coast *et al.* (1993), who reported that synthetic F2 had no stimulatory activity on a single *L. migratoria* MT in a conventional Ramsay assay, although Locmi-DH (a CRF-like peptide) had potent activity. Later, Montuenga *et al.* (1996) showed that there are endocrine cells in the ampulla of *L. migratoria* that contain not only Locmi-DH, but a second, as yet uncharacterized peptide, which is recognized by a Locmi-DH antiserum but is faster eluting on RPLC than the latter peptide. It is conceivable that the "AVP-like DH" may stimulate the release of Locmi-DH from these endocrine cells. The localization of AVP-like immunoreactivity has been determined in the locust (Thompson *et al.*, 1991); the titer of AVP-like immunoreactivity changes in the hemolymph in response to unknown stimuli and neurons containing it innervate nonocular photoreceptors (Thompson and Bacon, 1991). Analysis by RPLC of AVP-like containing neurons showed them to contain not only the antiparallel dimer F2, but also the parallel dimer and the monomer F1 (Baines *et al.*, 1995). Thus, there is strong evidence that the AVP-like factor is a *bona fide* neuropeptide, although its role remains controversial.

3.10.3.8. Other Peptides with Diuretic Activity

Skaer *et al.* (2002) tested three different tachykinin-related peptides (TRP) on MT of pharate adult

M. sexta: locustatachykinin-1 from *L. migratoria* (Locmi-TK-1; GPSGFYGVRamide; Schoofs *et al.*, 1993) and two TRPs from *L. maderae* (Leuma TRP-1, APSGFLGVRamide; and Leuma-TRP-4, APSGFMGMRamide; Muren and Nässel, 1996). Each TRP was tested at four concentrations from 1 nmol l^{-1} to 1 μmol l^{-1}. Each TRP exhibited a dose dependent increase in the rate of fluid secretion, but a maximal response was reached only 30–40 min after application. While no EC_{50} values were measured, they appeared to be in the range of 10–100 nmol l^{-1}. Leuma-TRP-1 gave the highest maximal secretion of the three; at 1 μmol l^{-1}, it increased the rate of fluid secretion 2.83-fold compared to that of the control. In contrast to the CAPs and leucokinin, TRP effects on tubule secretion activity were not long lasting. Two cardioactive peptides of as yet unknown sequence, CAP_{1a} and CAP_{1b} (Tublitz *et al.*, 1991), strongly stimulate *M. sexta* MT; there is a distinct probability they could be kinins. The very slow response (20–30 min delay) observed as a result of treatment of tubules with all agonists may be attributable to their use of 8–12 cm long pieces of a single MT (Skaer *et al.*, 2002); *M. sexta* tubules tend to collapse on dissection and the delay in fluid secretion may result from the filling time of the tubule (G.M. Coast, unpublished data).

Recently, Locmi-TK-1 has been reported to have an EC_{50} of 1.2 nmol l^{-1} in *L. migratoria*, with an identical value reported for *S. gregaria* (Johard *et al.*, 2003). The response observed was about 75% of that observed in response to treatment with Locmi-DH; the latter was found to have synergistic activity with both Locmi-TK-1 and serotonin. In light of the response observed to this peptide in these two distantly related species (*M. sexta* versus locusts), further studies of the effects of these peptides will be of very great interest.

Three fractions were isolated from a head extract of *A. aegypti* by RPLC based on their effect on the transepithelial potential (TEP) of isolated perfused MT (Petzel *et al.*, 1985). Each fraction contained a pronase-sensitive peptide with M_r values estimated by gel filtration chromatography to be 2400 (fraction I), 2700 (fraction II), and 1860 Da (fraction III) (Petzel *et al.*, 1986). Fraction I depolarized the TEP. While it has no effect on fluid secretion, it increases tritiated water (THO) loss and urine output from intact flies, possibly by inhibiting fluid uptake from the hindgut (Wheelock *et al.*, 1988). Fraction II also depolarized the TEP, with a biphasic response; the TEP first depolarized, and then hyperpolarized. Fractions II and III both have diuretic activity and selectively stimulate secretion of NaCl-rich urine. Fraction III was the more potent of these two; its diuretic and natriuretic activity were indistinguishable from that of exogenous cyclic AMP, although the latter only hyperpolarized the TEP (Petzel *et al.*, 1985). Fraction III was named mosquito natriuretic peptide (MNP) and was shown subsequently to stimulate cyclic AMP production in isolated tubules (Petzel *et al.*, 1987). Hegarty *et al.* (1991) found that dibutyryl cAMP stimulated Na^+ secretion from *A. aegypti* MT, with a concomitant decrease in K^+ secretion. Unfortunately, this factor is still unidentified.

3.10.3.9. Serotonin and Other Biogenic Amines

The biogenic amine serotonin (5-hydroxytryptamine; 5HT) is known to stimulate diuresis in a variety of insects, including *R. prolixus* (Maddrell *et al.*, 1969), *L. migratoria* (Morgan and Mordue, 1984; cAMP independent), *P. brassicae* (Nicolson and Millar, 1983), and *M. sexta* (Skaer *et al.*, 2002). In most cases, levels required for stimulation are high: in *R. prolixus*, it stimulates distal tubules up to 1000-fold via a cAMP dependent mechanism with EC_{50} ~30–40 nmol l^{-1} (Maddrell *et al.*, 1993a), whereas the response of *L. migratoria* tubules is only 25% of the maximum obtained with a CC extract and is mediated by a different second messenger, possibly Ca^{2+} (EC_{50} 10–100 nM; Morgan and Mordue, 1984). The response of *A. aegypti* tubules to serotonin varies with the stage of development. In larvae, it acts via cAMP to stimulate maximal secretion (EC_{50} ~100 nM; Clark and Bradley, 1996; Clark *et al.*, 1998a). In contrast, the response of adult tubules is ~25% of maximal (EC_{50} ~1 μM) and both cAMP and inositol trisphosphate (IP_3) production are increased (Veenstra, 1988; Cady and Hagedorn, 1999b). In *M. sexta* four concentrations were studied; while no EC_{50} value was reported, it appears to be in the range of 100–300 μmol l^{-1} (Skaer *et al.*, 2002). Octopamine also stimulates *M. sexta* tubules, but is much less potent. Fournier *et al.* (1994) reported that serotonin has antidiuretic effects in the rectum of *L. migratoria*.

Recently, Blumenthal (2003) has shown tyramine to be a potent stimulant of *D. melanogaster* MT, acting at levels as low as 1 nmol l^{-1}. Tyramine is several orders of magnitude more active than octopamine or dopamine. Interestingly, tyramine is produced in the MT from tyrosine taken up from the hemolymph, or culture medium, via tyrosine decarboxylase, and a tyramine receptor is also expressed in MT of this species. Tyramine is believed to play an autocrine or paracrine role; it causes fluctuations in the basolateral membrane transepithelial potential.

Clearly this discovery merits studies in other species; this is the first demonstration of a physiological role for a tyramine receptor in *D. melanogaster* (Blumenthal, 2003).

3.10.3.10. Antidiuretic Factors Inhibiting Malpighian Tubule Secretion

Spring *et al.* (1988) characterized an antidiuretic hormone from hemolymph of *A. domesticus* kept under very dry conditions; an extract of this hemolymph inhibited secretion by MT of control insects. Hemolymph extract from insects reared under normal humidity did not inhibit MT secretion. Until recently, no factor had been isolated with such activity. Lavigne *et al.* (2001) published a partial purification of a factor from *Leptinotarsa decemlineata* through five RPLC steps using only two different columns. The protocol they used involved minimal changes of parameters between successive purifications, and utilized evaporation steps between RPLC purifications likely to result in poor recovery. While no peak was visible in the final separation step, they reported that the apparent molecular size of the factor (estimated by dialysis) was in the range of 25–50 amino acids. The first factor to be identified that inhibits MT secretion, Tenmo-ADFa, was isolated from pupal heads of *T. molitor*, based on its ability to elevate cyclic GMP (cGMP) levels in MT of this species. Tenmo-ADFa was found to be a 14-mer with the sequence VVNTPGHAVSYHVY-OH, lacking the amidation usually found in regulatory peptides. It is exquisitely potent with an EC_{50} of 10 fmol l^{-1} (0.01 pmol l^{-1}) (Eigenheer *et al.*, 2002), but receptor downregulation occurs at high concentrations (such as 1 nmol l^{-1}!). A second factor isolated from the same source, Tenmo-ADFb, is a 13-mer with the sequence YDDGSYKPHIYGF-OH, again nonamidated. It is 24 000 times less potent than Tenmo-ADFa, but still has $EC_{50} = 0.24$ nmol l^{-1} (Eigenheer *et al.*, 2003). These factors have poor solubility in the acidic solvents usually used for extracting neuropeptides from tissues. Following typical isolation protocols resulted in low yields. However, upon discovering that the bulk of the activity remained in the pellet from acid extraction, the pellet was extracted with a neutral solvent, which by then had so many impurities removed that only three RPLC purification steps were required to purify the factors from the neutral extract to homogeneity. Curiously, these factors have extremely high sequence similarity to two cuticular proteins of this beetle: Tenmo-ADFa is identical to the C-terminus of the protein CAA03880 (Mathelin *et al.*, 1998) at all residues, except that Thr4 in the peptide is an Ala residue in the protein (**Figure 9**). Tenmo-ADFb is 100% identical with the 13 C-terminal residues of *T. molitor* putative cuticle protein 9.2 (TmPCP9.2) (Baernholdt and Andersen, 1998). Consequently, the identification of ADFb was not published until immunohistochemical evidence showed specific staining for Tenmo-ADFb-like material in two pairs of bilaterally symmetrical neurosecretory cells of the protocerebrum of *T. molitor* (Eigenheer *et al.*, 2003). While the cuticle protein TmPCP9.2 lacks obvious enzymatic cleavage sites upstream of the portion identical with ADFb, this identity suggested the possibility that it could be a proteolysis fragment of the cuticle protein, and that this fragment might have coincidental biological activity. Tenmo-ADFa does have an interesting sequence identity to big endothelin 1 (**Figure 9**). The sequence identity to rabbit endothelin 1 (8 residues) and human endothelin 1 (7 residues) begins at exactly that bond where endothelin converting enzyme cleaves big endothelin into the potent vasoconstrictor endothelin 1. This cleavage site is marked with an arrow in **Figure 9**.

Recently Coast (unpublished data) has found that *M. sexta* allatotropin (Kataoka *et al.*, 1989a; Manse-AT) inhibits the Manse-DH stimulated secretion of fluid by larval MT of this species at 50–200 nmol l^{-1} levels. This is the same concentration found earlier to inhibit fluid uptake from the anterior midgut (Lee *et al.*, 1998) of *M. sexta*.

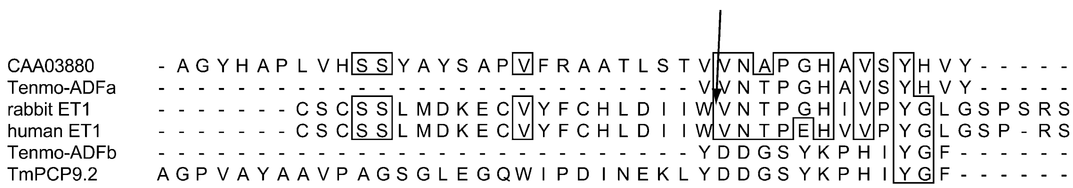

Figure 9 Two antidiuretic factors from *Tenebrio molitor*: Tenmo-ADFa and Tenmo-ADFb. Tenmo-ADFa is identical at all but one residue with the C-terminus of the cuticle protein CAA03880 from this species (Mathelin *et al.*, 1998), and Tenmo-ADFb is 100% identical with the 13 C-terminal residues of another cuticle protein from this species, TmPCP9.2 (Baernholdt and Andersen, 1998). In addition, Tenmo-ADFa has an interesting sequence identity with big endothelin 1, a precursor of the potent vasoconstrictor endothelin 1. Endothelin converting enzyme cleaves big endothelin at the bond indicated by an arrow in the figure; this is exactly where the sequence identity with ADFa commences. Thus, the identity is to the apparently inactive endothelin fragment removed in processing.

Incubation of 1 nmol l^{-1} Manse-DH with and without 50 nmol l^{-1} Manse-AT (E. Chidembo and D.A. Schooley, unpublished data) shows that Manse-AT seems to act via lowering cAMP levels.

3.10.3.11. Antidiuretic Factors that Promote Fluid Reabsorption in the Hindgut

Hormonal control of fluid reabsorption in the hindgut has been heavily studied in locusts (*S. gregaria* and *L. migratoria*). Three neuropeptides have been either isolated or characterized from the CC of locusts (reviews: Phillips *et al.*, 1988, 1986): neuroparsins, ion transport peptide (ITP), and chloride transport stimulating hormone (CTSH). Only the first two have been fully sequenced; CTSH is labile to the usual conditions used for RPLC isolation of peptides, due to its instability in acidic conditions.

Herault *et al.* (1985) reported that the nervous and glandular lobes of the CC of *L. migratoria* each contain a factor acting as an ADH on the rectum; these factors differ in size and extraction properties. The glandular lobe (GCC) factor was not purified, but Herault and Proux (1987) reported that GCC extracts cause a peak in rectal tissue cAMP levels coinciding with elevated short circuit current (I_{sc}). This stimulation is mimicked by forskolin, a stimulant of adenylate cyclase. The factor from the CC was reported to be a neuroparsin (Np), because all antidiuretic activity in crude CC of *L. migratoria* was abolished by an antibody to this neuropeptide (Herault *et al.*, 1988). Neuroparsins are proteins (NpA, NpB) isolated and sequenced from CC of *L. migratoria* (Girardie *et al.*, 1989, 1990). They have also been reported to have hypertrehalosemic (Moreau *et al.*, 1988) and antijuvenile hormone activity (Girardie *et al.*, 1987). NpB was reported to be a homodimer of a 78-residue polypeptide. NpA is identical to NpB except for having a heterogeneous N-terminus, the longest form of which has 83 residues. NpB is thought to be formed from NpA by enzymatic cleavage of the N-terminal sequence. Subsequently Hietter *et al.* (1991) confirmed the sequences of these small proteins, including the N-terminal heterogeneity, but revised the structural assignment for neuroparsins involving three internal disulfide bridges, in which the chains are monomeric. Fournier (1991) presented a body of data consistent with NpB acting on rectal fluid reabsorption by stimulating the inositol phosphate (IP) cascade with subsequent elevation of cytosolic Ca^{2+}. They concluded that neuroparsins are the only ADH in *L. migratoria* GCC and that these peptides act via the IP-Ca^{2+} second messenger system, whereas serotonin from the NCC acts on the rectum via a cAMP mediated Ca^{2+} increase (Fournier *et al.*, 1994). They did not study actions of purified or synthetic Nps on rectal solute transport processes. Jeffs and Phillips (1996) found no effect of Locmi-Nps on either rectal ion or fluid transport in the locust *S. gregaria*. They attributed this either to fundamental differences in transport properties in these closely related insects or, more likely, to the use of Cl^--free saline in the assay used (Fournier *et al.*, 1987) for preincubation of everted rectal sacs for 1 h.

Chloride transport stimulating hormone, a peptide occurring in the CC of *S. gregaria*, was characterized by its ability to increase short circuit current in *S. gregaria* rectal sheets maintained in Ussing chambers (Phillips *et al.*, 1980). In this assay, either cAMP or CC extracts give a ten-fold increase in I_{sc} for >8 h after stimulation. A single zone is seen on size exclusion chromatography with M_r of about 8000 Da. The peptide nature is proved by its sensitivity to trypsin, and it is active at what appear to be nmol l^{-1} concentrations (Phillips *et al.*, 1986). The peptide can be extracted with water, saline, and aqueous ethanol, but biological activity is lost rapidly below pH 6. This may be consistent with the presence of an Asp-Pro bond in the primary sequence, which, as mentioned in Section 3.10.3.3, is suspected of causing an inability to isolate two CRF-like DH by RPLC techniques as well. Proux *et al.* (1985) provided some evidence that CTSH is produced in the pars intercerebralis and is transferred down nerves to the glandular lobe of the CC, after passing through the nervous lobe of the CC. CTSH is similar in size to Locmi-Nps, but is distinguished from the latter by the stability of Locmi-Nps to acidic conditions. Also, Locmi-Nps are reported to act via stimulation of phospholipase C.

Audsley and Phillips (1990) used an assay similar to that for CTSH, substituting locust ileum for rectum, and found stimulants of ion transport in both the CC and the ventral ganglia. The effects elicited by CC and ganglia extracts differ in properties. The factor in the CC, unlike CTSH, is stable to acid. This stability led to its successful isolation by RPLC, and a partial sequence was obtained to 31 amino acids (Audsley *et al.*, 1992b). This peptide was christened ion transport peptide (Schgr-ITP), to distinguish it from CTSH. It was found to be 44–59% identical to the crustacean hyperglycemic (CHH), molt inhibiting (MIH), and vitellogenesis inhibiting (VIH) hormones, a group of highly related 72 amino acid peptides (Audsley *et al.*, 1992b). This was the first direct evidence for the existence of a peptide related to this family outside crustaceans. Audsley *et al.* (1992a) tested purified Schgr-ITP on the rectum and found that it had weak effects on short circuit

current compared with CTSH, and no effect on the rate of fluid reabsorption. They concluded that separate neuropeptides act on the ileum and rectum of the locust.

Meredith *et al.* (1996) used degenerate primers designed from the partial protein sequence to clone by PCR a partial sequence of Schgr-ITP from a brain cDNA library. Use of 5′ and 3′ rapid amplification of cDNA ends (RACE) strategies led to isolation of a cDNA of 517 bp encoding a complete open reading frame for Schgr-ITP prepropeptide of 130 amino acid residues (Meredith *et al.*, 1996). The prepropeptide has a 55-residue signal peptide and a dibasic cleavage site preceding the start of the partial ITP sequence determined by Audsley *et al.* (1992b). The C-terminal Leu is followed by Gly-Lys-Lys-stop, which is consistent with C-terminal amidation and a second dibasic cleavage site to give the complete ITP sequence of 72 amino acid residues. Meredith *et al.* (1996) also used ITP cDNA sequence primers to probe a locust ileal mRNA library, and isolated an ITP-like clone, which was sequenced. It was identical to the brain cDNA for ITP except for an additional 121 bp insert at amino acid position 40 of ITP, suggesting alternative C-termini splicing of genomic DNA. The open reading frame for ITP-L (134 residues) is four residues longer than that of ITP (**Figure 10**). All six cysteines are conserved. The unique C-terminus of ITP-L has only 14 of the last 36 amino acid residues in common with ITP, most of the difference being over the last 20 residues. Using reverse transcriptase PCR (RT-PCR) techniques, ITP-L mRNA was detected in tissues (flight muscle, hindgut, and MTs) whose extracts have no stimulatory effect in the locust ileal I_{sc} bioassay, while ITP mRNA was found only in the brain and CC, which do stimulate ileal I_{sc}. The ITP-L peptide does not stimulate the locust ileal I_{sc} bioassay, but acts as a weak antagonist (Wang *et al.*, 2000). The Schgr-ITP synthesized by solid-phase peptide synthesis was oxidized to the appropriately folded form with three disulfide bonds (King *et al.*, 1999); this was found to exhibit biological actions identical to that of the native peptide isolated from tissue.

While in the 1990s there was concern over conflicts in results between the proponents of neuroparsins versus Schgr-ITP, three publications in the area of crustacean neuroendocrinology strongly support the role of ITP as an authentic osmoregulator (see **Chapter 3.16**). Chung *et al.* (1999) reported a large, precisely timed release of CHH from gut endocrine cells in the crab *Carcinus maenas* at ecdysis. This release appears to trigger the water and ion uptake required during molting, which allows the swelling necessary for successful ecdysis and the subsequent increase in size during postmolt. The endogenous ortholog of CHH of the freshwater crayfish *Pachygrapsus marmoratus* (Spanings-Pierrot *et al.*, 2000) has been shown to play a crucial role in control of gill ion transport. In the crayfish *Astacus leptodactylus*, injection of CHH was found to increase the hemolymph osmolality and Na^+ concentration 24 h after injection (Serrano *et al.*, 2003). Two other CHH related peptides caused a smaller increase in Na^+ concentration.

Liao *et al.* (2000) characterized one of two factors that separate on RPLC of brain–CC–corpora allata extracts of larval *M. sexta*. These factors trigger fluid reabsorption in an everted rectal sac bioassay with *M. sexta*. Owing to the cryptonephric anatomy of larvae of this species, the CRF-like peptide Manse-DH also causes rectal fluid reabsorption. However, the effect of Manse-DH is blocked by bumetanide (an inhibitor of the Na^+–K^+–$2Cl^-$ cotransporter), bafilomycin A_1, and amiloride, while that of the more potent of the two factors, Manse-ADFB, is not blocked by any of these inhibitors. The Cl^- channel blockers 4,4′-diisothiocyanatostilbene-2, 2′-disulforic acid disodium salt (DIDS) and diphenylamine-2-carboxylic acid (DPC) both block

Figure 10 Alignment of Schgr-ITP with its *Bombyx mori* (Bommo-) and *Drosophila melanogaster* paralogs (Clustal W, V. 1.8), as well as the variant form Schgr-ITPL. Boxed residues are identical. Also shown are the highly similar *Carcinus maenas* (Carma-) crustacean hyperglycemic hormone, and *Homarus americanus* (Homam-) molt inhibiting hormone. All peptides are amidated at the C-terminus (denoted by lower case a); the two crustacean peptides are blocked at the N-terminus with pQ (pyroglutamate) residues.

the action of Manse-ADFB, as does H-89, a potent and specific inhibitor of protein kinase A. These data suggest that this factor of still unknown structure has a mechanism of action similar to Schgr-ITP. Homologs of ITP have been identified in *B. mori* (Endo *et al*., 2000) and in the genome of *D. melanogaster* (**Figure 10**): While neither has been synthesized or subjected to an activity assay, combined with the data on osmoregulatory effects of CHH, it seems likely that Manse-ADFB is similar to this family of peptides.

3.10.3.12. Cellular Mechanisms of Action

3.10.3.12.1. Introduction Does the diverse control of tubule secretion between different orders, and even between similar species belonging to the same order, have any rationale? Do differences in hemolymph composition, diet (and hence ion uptake), water availability, and the structure of the excretory system explain the diverse control strategies employed by different species? Primitive insect orders have a hemolymph characterized by a high concentration of Na^+ relative to K^+, and the sum of total anions and cations accounts for a considerable part of the total osmolarity (Sutcliffe, 1963). In contrast, more highly evolved insect orders have a greater proportion of hemolymph osmolarity attributable to high levels of amino acids and organic acids and, in some (Lepidoptera, Hymenoptera, and certain Coleoptera; Sutcliffe, 1963), K^+ is the dominant cation, with elevated concentrations of Mg^{2+} and Ca^{2+}. Since tubule secretion is driven by secondary active cation transport, differences in hemolymph composition might place some constraint on how fluid secretion is regulated. The same could apply to the dietary intake of ions, most notably K^+ and Na^+. If the diet is K^+-rich, as in herbivorous insects, then it is appropriate for K^+ to be the dominant cation secreted by the MT and to control secretion by manipulating the rate of K^+ transport. Conversely, hematophagous insects take infrequent blood meals, which imposes a considerable challenge on the excretory system for the removal of imbibed salt (NaCl) and water.

Not surprisingly, the MTs of mosquitos (*A. aegypti*) respond to released diuretics with a dramatic increase in secretion driven by a switch from K^+ transport to Na^+ transport (Beyenbach, 2003). Hence, the diuretic hormone (so far unidentified, but thought to be a CRF-like or CT-like DH) exerts both diuretic and natriuretic activity. Interestingly, in the laboratory, the same mechanism has been shown to operate in the tubules of male mosquitos (Plawner *et al*., 1991), which do not feed on blood but on nectar (Clements, 1992), resulting in a diet that is not rich in NaCl. Periods of diuresis that do not require a concomitant natriuresis must be initiated by the release of a different DH, possibly a myokinin, which, because it stimulates anion movement, has a neutral effect on cation transport. Can a similar story be developed for other species? *D. melanogaster* feeds on fermentation products (the alcoholic of the Insecta!), whereas the closely related *M. domestica* imbibes a mixture of saliva and the products of extracorporal digestion. A major drawback in this analysis is that most researchers have studied effects on fluid secretion rather than on ion transport. Peptides with apparently similar diuretic activity could well differ in their effect on urine composition and hence on ion transport (the product of concentration and the rate of secretion). An early demonstration of the possibility of such an occurrence is in MT of *A. aegypti* treated with bumetanide, a drug that inhibits the Na^+–K^+–$2Cl^-$ cotransporter stimulated by cAMP. Bumetanide treatment has little effect on basal fluid secretion, but decreases K^+ secretion with a concomitant increase in Na^+ secretion (Hegarty *et al*., 1991). Coast (1995) has shown that Locmi-DH (CRF-like) and locustakinin have fairly similar diuretic potency, but have quite different effects on ion transport. The majority of physiological studies to date on the action of synthetic peptides affecting MT function have focused on cellular effects, such as elevation of second messengers, or on fluid transport. Relatively few have focused on the effects of synthetic factors on ion transport, which, given the complex interplay of factors controlling fluid and ion homeostasis in vertebrates, is a serious omission. Moreover, in the cricket *Teleogryllus oceanicus*, the distal portion of the MT have been reported to secrete a hyperosmotic urine containing 125 mM Mg^{2+}, together with a lesser concentration of Na^+ (Xu and Marshall, 1999). There are few studies on Mg^{2+} transporters in insect systems, yet in a number of insect species with high hemolymph K^+, the concentration of Mg^{2+} is actually higher (Sutcliffe, 1963; Cohen and Patana, 1982; Dow *et al*., 1984). Thus, data on specific ion transport is an underinvestigated area likely to shed some light on why so many peptides are involved in control of water and salt balance in insects.

Water availability may also play a role in determining the cocktail of diuretics and antidiuretics used to control tubule secretion. The simplistic view that diuretics stimulate tubule secretion whereas antidiuretics increase fluid reabsorption in the hindgut is no longer tenable (at least in some species). To date, antidiuretic activity inhibiting the MT has been identified in three species. In *R. prolixus*,

the antidiuretic activity of CAP_{2b} has been linked to the need to rapidly turn off tubule secretion (Quinlan *et al*., 1997). Normally, the rapid degradation of a DH (probable half-life in the circulation measured in minutes) (Li *et al*., 1997) would suffice to end a period of diuresis. The situation in *R. prolixus* is very different, however, because the DH has such a dramatic effect on secretion, which at maximal rates would be sufficient to deplete the total store of water in the hemolymph within minutes. Under these conditions, it is essential that diuresis be switched off coincident with reduced fluid uptake from the midgut (Quinlan *et al*., 1997), and the insect now conserves water until the next blood meal.

In this respect, *R. prolixus* resembles a xeric insect in the period between its intermittent blood meals. It is of considerable interest that another insect shown to use antidiuretic factors to control tubule secretion is *T. molitor*, an extreme example of a xeric species able to survive very dry conditions (O'Donnell and Machin, 1991). In both *T. molitor* and *R. prolixus* (for which a native antidiuretic factor has still to be identified), antidiuresis appears to result from the activation of a cGMP dependent cAMP phosphodiesterase, which lowers intracellular levels of cAMP, the second messenger used by both CRF-like and CT-like DH. Not surprisingly, the antidiuretic factors of *T. molitor* are extremely potent (Eigenheer *et al*., 2002, 2003) and effectively counter the diuretic activity of native CRF-like DH (Wiehart *et al*., 2002). To grasp the importance of this, it is important to note that coleopteran larvae and adults have a cryptonephric system in which the distal ends of the MTs are closely associated with the rectum (Ramsay, 1964; Section 3.10.3.12.7). Fluid is reabsorbed from the rectum into the cryptonephric region of the tubules and flows into the gut at the midgut–hindgut junction, where it is postulated to move anteriorly directed and to moisten the dry food for digestion prior to reabsorption by the midgut (Nicolson, 1991). To gain water (the cryptonephric system is used to take up water from subsaturated atmospheres), fluid absorption from the free portion of the tubules must exceed fluid secretion, although these two processes could be taking place in functionally different segments. Unfortunately, nothing is known of fluid reabsorption from *T. molitor* tubules or whether antidiuretic factors have any effect on urine composition. Recent work (G.M. Coast, unpublished data) with MT from *M. sexta* larvae, which also have a cryptonephric system, shows that one segment (the yellow segment) can display net secretion or net reabsorption depending on the composition of the bathing fluid and the complement of peptides present. The two processes appear to be proceeding in parallel, with the overall balance tilted towards secretion or reabsorption by stimulants of each activity. The likelihood must be that similar mechanisms operate in *T. molitor* tubules.

3.10.3.12.2. CRF-like DH:cellular actions The CRF-like DHs studied to date all elevate cAMP in response to treatment of MT *in vitro*. As noted by Rafaeli *et al.* (1984), the cAMP is usually released from the tubule, which allows assay of the medium without having to homogenize and extract the tubules. This fact facilitates *in vitro* assays for isolating new members of this family. When using conspecific assays, CRF-like DH stimulate secretion by MTs of *A. domesticus* (Coast and Kay, 1994), *L. migratoria* (Patel *et al*., 1995), *D. punctata* (Furuya *et al*., 2000b), *M. domestica* (Iaboni *et al*., 1998), *T. molitor* (both Tenmo-DH_{37} and Tenmo-DH_{47}) (Wiehart *et al*., 2002), and both CRF-like DH of *M. sexta*, Manse-DH (Audsley *et al*., 1993, 1995), and Manse-DPII (Blackburn and Ma, 1994) at low nanomolar concentrations. Diuretic activity varies among species, from a maximal response in *A. domesticus* (Coast and Kay, 1994), equivalent to that obtained with a CC extract, to <25% of a maximal response in *M. domestica* (Iaboni *et al*., 1998), and probably depends upon whether anion or cation transport is the rate-limiting step in tubule secretion.

The potency of CRF-like DH varies much more in heterologous assays. Tubules of *M. sexta* are extremely flexible in cross-reacting with all members of the CRF-like DHs tested (Audsley *et al*., 1995), with the exceptions noted of the free acid form of Manse-DH and the two DHs of *T. molitor*, which have free acids at the carboxyl terminus. In contrast, tubules of *L. migratoria* seem to be very selective for their endogenous ligand; Peram-DP has an EC_{50} over 300-fold higher than Locmi-DH, and other ligands were less effective (Audsley *et al*., 1995). The CRF related peptide of *Culex salinarius* (Culsa-DH) has weak diuretic and natriuretic activity in *A. aegypti* (Clark *et al*., 1998b), compared with the pronounced effects of an unidentified head factor, mosquito natriuretic peptide (MNP). Culsa-DH appeared to elevate intracellular Ca^{2+} at $nmol\,l^{-1}$ concentrations, but to activate adenylate cyclase at ~100 $nmol\,l^{-1}$ levels (Clark *et al*., 1998b). These data are based upon the electrophysiological signatures of the peptide being mimicked by thapsigargin and cAMP: the response to Culsa-DP is biphasic with thapsigargin mimicking the initial depolarization at $nmol\,l^{-1}$ concentrations of peptide, and cAMP reproducing the subsequent

hyperpolarization at ~100 nmol l^{-1} levels of Culsa-DP. However, this work involved a cross-species assay, and preliminary data for synthetic Anoga-DH_{44} (G.M. Coast, K.M. Schegg, and D.A. Schooley, unpublished data) using *A. gambiae* MT suggest that this CRF related DH may have a major role in the postblood meal diuresis of this species.

The increase in cAMP is believed to activate a bumetanide sensitive Na^+–K^+–$2Cl^-$ cotransporter (see **Figure 11**) in *M. sexta* (Audsley *et al.*, 1993), *R. prolixus* (O'Donnell and Maddrell, 1984; Ianowski and O'Donnell, 2001; Ianowski *et al.*, 2002), *A. domesticus* (G.M. Coast, unpublished data), and adults of *A. aegypti* (Beyenbach, 2003), but not in larval tubules (Clark and Bradley, 1996). The Na^+–K^+–$2Cl^-$ cotransporter has been cloned from *M. sexta* (Reagan, 1995b); it is a large protein with 12 putative transmembrane helices resembling orthologous proteins from other species, and it contains a consensus site for phosphorylation by protein kinase A (Reagan, 1995b). Similar transporters encoded in the *D. melanogaster* genome (CG2509 and CG31547) lack the protein kinase A site (Ser1025) reported by Reagan (1995b), which might explain the relatively low sensitivity of this species to the CRF-like DH compared with kinins. Thr963 in the *A. gambiae* transporter (XM307782) is a likely protein kinase A site (determined with the program NetPhos 2.0 at the Center for Biological Sequence Analysis, Technical University of Denmark; NetPhos, 2004). This program uses neural network predictions for serine, threonine, and tyrosine phosphorylation sites in eukaryotic proteins.

3.10.3.12.2.1. CRF-like DH receptors Reagan (1994) utilized expression cloning to deduce the sequence of a receptor from *M. sexta* (Manse-DHR), and subsequently a similar one from *A. domesticus* (Reagan, 1996) (Achdo-DHR). Two orthologs of these receptors are encoded in the *D. melanogaster* genome (CG8422 and CG12370); recently one of these (CG8422) was shown to be the receptor (Drome-DHR) for Drome-DH_{44} (Johnson *et al.*, 2004). A BLAST search of the *A. gambiae* genome using the Manse-DHR as a query returned a highly similar receptor (XM 315466) tentatively denoted in **Figure 12** as Anoga-DHR. All are members of Family B of seven transmembrane domain

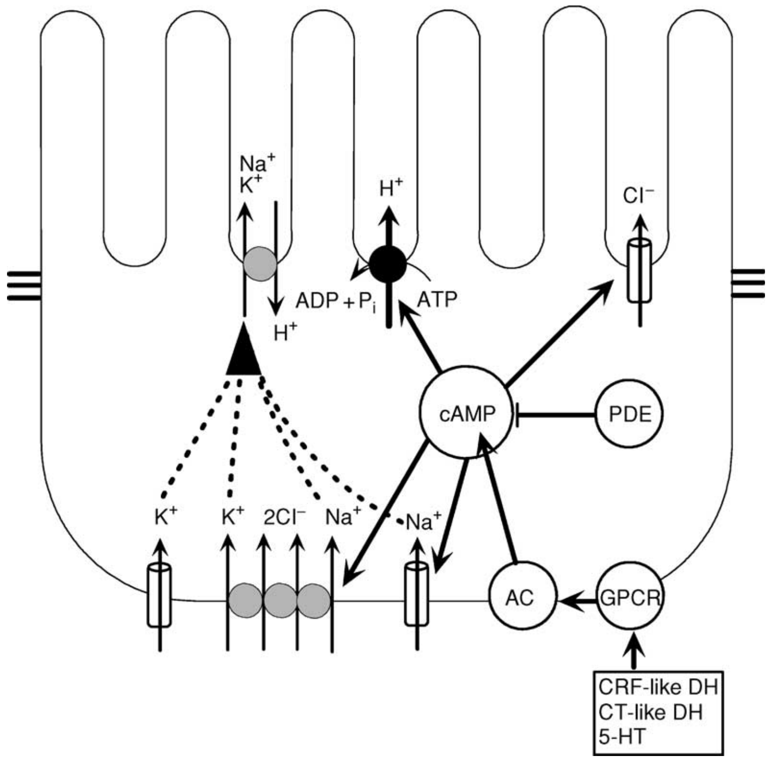

Figure 11 Proposed actions of cAMP in principal cells. CRF related DH, CT-like DH, and serotonin stimulate adenylate cyclase (AC) activity and increase intracellular levels of cAMP. Diuresis results from the stimulation of ion transport by cAMP which, depending on species, activates the apical membrane V-ATPase (*Drosophila melanogaster*, *Tenebrio molitor*, and *Rhodnius prolixus*), increases Na^+–K^+–$2Cl^-$ cotransport (*R. prolixus*, *Manduca sexta*, *Aedes aegypti*, and *Acheta domesticus*) and opens a Na^+ selective conductance in the basolateral membrane (*A. aegypti*). In addition, cAMP opens an apical membrane Cl^- conductance in *R. prolixus* tubules. Cyclic AMP levels are reduced by phosphodiesterase activity, which may account for the antidiuretic effects of Tenmo-ADFa,b and CAP_{2b} (see text for details).

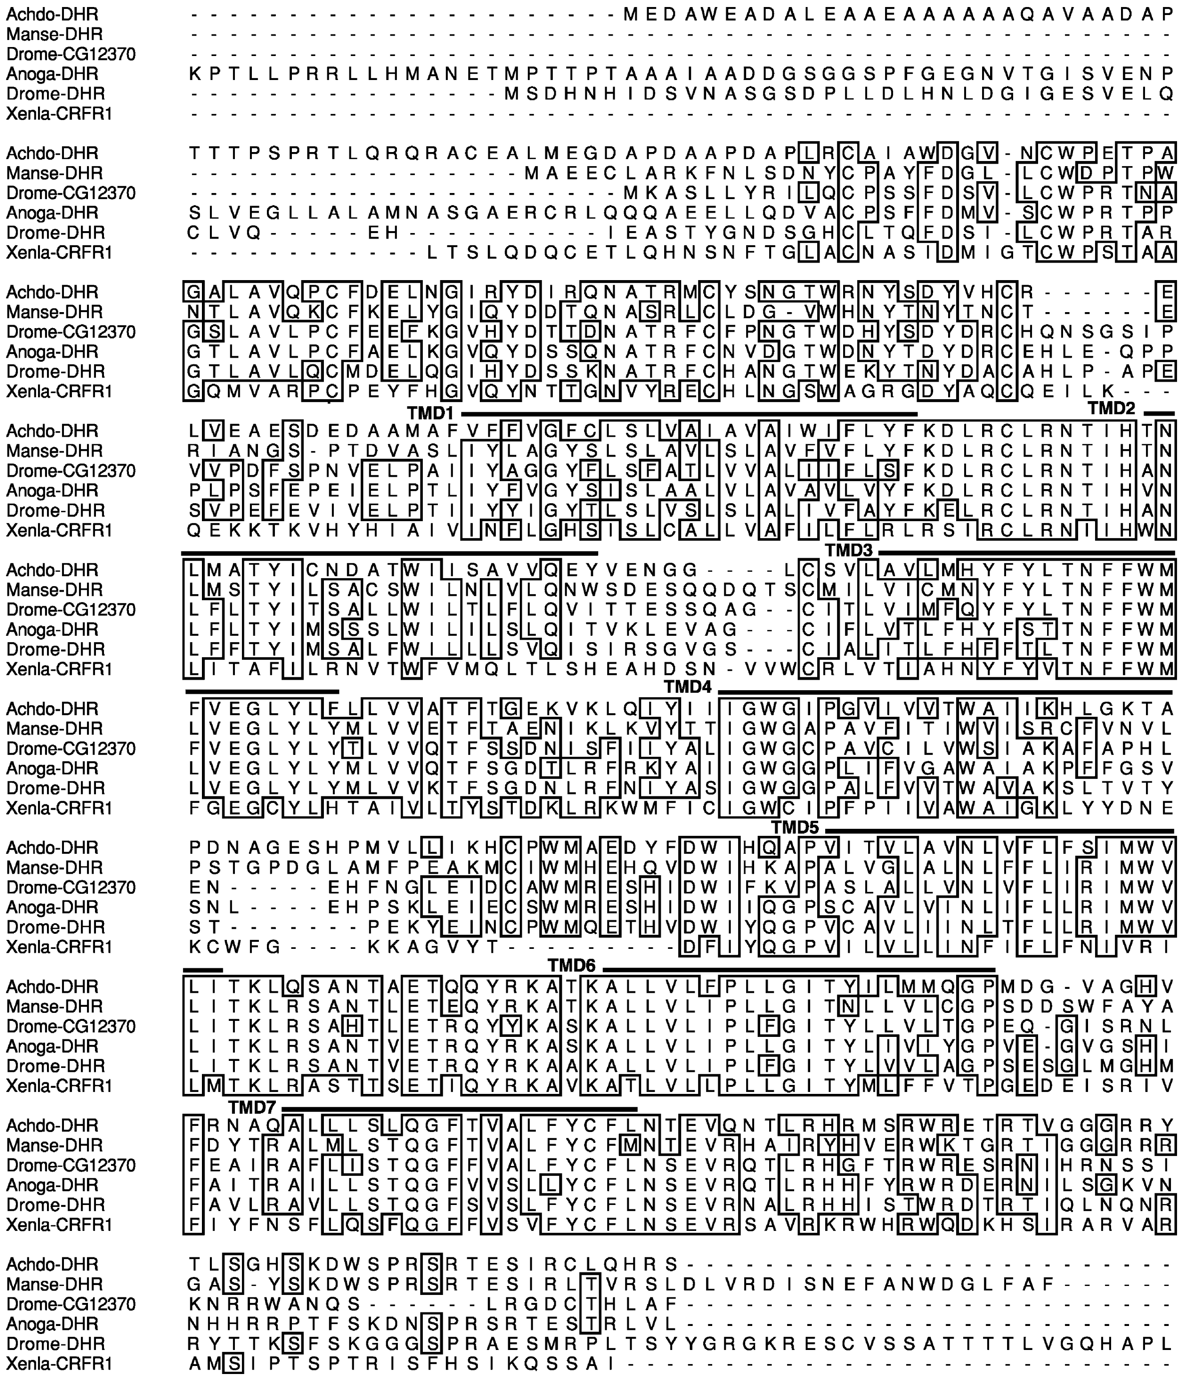

Figure 12 The CRF-like DH receptors are shown with identical residues boxed. Sequences were aligned with Clustal W, V. 1.8. The seven transmembrane domains (TMD) are indicated with a bold line and the domain number. Their approximate location was determined with the program TMHMM Server v. 2.0 at the Center for Biological Sequence Analysis, Technical University of Denmark (TMHMM, 2004). This program determines the location of transmembrane (TM) domains using hidden Markov models (HMM). The bold lines were determined for the *Manduca sexta* CRF-like DH receptor (Manse-DHR); for the *Drosophila melanogaster* CRF-like DH receptor (Drome-DHR) the location of the first TMD agreed exactly, whereas for the second it started and continued one residue downstream of that in Manse-DHR, for the third it started and continued one residue upstream, for the fourth it started and ended seven residues upstream of that in Manse-DHR, for the fifth it started seven residues upstream and ended one residue upstream of that in Manse-DHR, for the sixth it started three residues upstream and ended in the same position of that in Manse-DHR, and for the seventh it started five residues upstream and ended at the same position as that of Manse-DHR. The final 47 C-terminal residues of Drome-DHR are not shown for clarity. Drome-CG12730 is an orphan receptor with high similarity to this family of receptors. A homologous receptor is found in the genome of *Anopheles gambiae* (Anoga-DHR), and the *Acheta domesticus* DH receptor (Achdo-DHR) has been cloned (Reagan, 1996). The *Xenopus laevis* CRF1 receptor is shown for comparison.

G protein-coupled receptors (a family that includes the CRF receptors of vertebrates; Dautzenberg and Hauger, 2002). As in most receptor families, the transmembrane domains (TMD) are highly conserved (**Figure 12**). Other domains differ in their degree of similarity; intracellular domain 1 (between TMD 1 and 2) and domain 3 (between TMD 5 and 6) are quite highly conserved. In the CRF receptors, intracellular domain 3 is believed to be the site for G protein coupling (Hauger *et al.*, 2003). All of the CRF-like DH receptors have six Cys residues in the N-terminal extracellular domain, a structural feature that has been shown to be critical for ligand interaction in the CRF receptor (Qi *et al.*, 1997); the orphan receptor Drome-CG12730 has but five Cys in this domain. The location of five of these is completely conserved, while the Cys closest to the N-terminus is variable in position (**Figure 12**). The disulfide pairings in the CRF receptor have been inferred (Qi *et al.*, 1997); they will add a great deal of conformation rigidity to the N-terminal domain, believed to be key in CRF binding (Dautzenberg *et al.*, 1998), together with the fourth extracellular loop (Sydow *et al.*, 1997, 1999). Certain amino acid residues in the N-terminal domain of *X. laevis* (Dautzenberg *et al.*, 1998) and human (Wille *et al.*, 1999) CRF_1 receptors have been identified as crucial for ligand binding via site-directed mutagenesis. The intense research interest in these receptors has been driven in part by the development of small molecule antagonists of the receptors as drugs targeted at depression and anxiety (Kehne and De Lombaert, 2002); it is conceivable that a similar approach with agonists or antagonists of the insect receptors could lead to new insecticides.

It seems highly likely that separate receptors exist for the paralogous, shorter CRF-like DHs, Manse-DPII, Hylli-DH_{30}, and Tenmo-DH_{37}, but there is currently no evidence for this. The CRF_1 receptor binds both CRF and urocortin 1 (Hauger *et al.*, 2003), but discriminates against urocortin 2 and 3; whereas the $CRF_{2(a)}$, $CRF_{2(b)}$, and $CRF_{2(c)}$ receptors show a preference for urocortin forms over CRF (Hauger *et al.*, 2003). In *M. sexta*, both Manse-DH and Manse-DPII are active in adults *in vivo* (Kataoka *et al.*, 1989b; Blackburn *et al.*, 1991) as well as *in vitro* (Blackburn and Ma, 1994; Audsley *et al.*, 1995). However, in larvae only Manse-DH has been shown to be active; Manse-DPII is without apparent effect on the cryptonephric MT (Audsley *et al.*, 1995) and the ascending portion of the larval MT (G.M. Coast, unpublished data). Curiously, upon treatment of leaf slices with Manse-DPII, neonatal larvae of *M. sexta* behaved as though the peptide had antifeedant effects, and some mortality was observed at the ensuing molt (Ma *et al.*, 2000). Similarly, Keeley *et al.* (1992) showed that injection of last instar larvae of *Heliothis virescens* with synthetic Manse-DH had an antifeedant effect in addition to effects on fluid secretion; MT of larvae treated *in vitro* with this peptide showed increased fluid excretion. These actions are suggestive of effects of both peptides on receptors in sites likely to control feeding, such as the CNS.

3.10.3.12.3. Kinins: cellular actions Different models have been advanced for the mode of action of kinins in mosquitos versus fruit flies (see **Figure 13**). In both models, kinins bind to a cell membrane receptor, resulting in activation of phospholipase Cβ (PLCβ) and a rapid rise in intracellular Ca^{2+} ($[Ca^{2+}]_i$). The stellate cells of fruit fly tubules express a gene (CG10626) encoding a G protein-coupled kinin receptor (Drome-K-R). The binding of Drome-K to this receptor activates PLCβ and increases inositol (1,4,5)-trisphosphate (IP_3) production and $[Ca^{2+}]_i$ in S2 cells transfected with Drome-K-R (Radford *et al.*, 2002). Two *Drosophila* genes encode PLCβ (*norpA* and *Plc21C*) and Drome-K-stimulated diuresis is greatly reduced in tubules from *norpA* mutants (Pollock *et al.*, 2003). An increase in $[Ca^{2+}]_i$ precedes the fastest physiological response of tubules to kinin stimulation. It results from the release of Ca^{2+} from endoplasmic reticulum stores triggered by IP_3 binding a receptor (IP_3R) that is a ligand gated Ca^{2+} channel, and mutations of the IP_3R gene (*itpr*) attenuate kinin stimulated diuresis and the rise in $[Ca^{2+}]_i$ (Pollock *et al.*, 2003). CAP_{2b} peptides also use IP_3 as a second messenger in fruit fly tubules, but act on principal cells rather than stellate cells (see Section 3.10.3.12.4).

In marked contrast to the fruit fly, kinins act through a Ca^{2+} signaling pathway in principal cells of *A. aegypti* tubules (Yu and Beyenbach, 2002). The molecular genetic tools available for *D. melanogaster* are not yet available for mosquitos, but Beyenbach's group has shown that the distinctive electrophysiological signature accompanying kinin stimulation, namely depolarization of the transepithelial potential (V_{tep}) and a reduction in transepithelial resistance (R_t), are identical in tubule segments with and without stellate cells (Yu and Beyenbach, 2004). Indeed, the fact that it is possible to measure increased levels of IP_3 in intact tubules of *A. aegypti* challenged with Aedae-Ks (Cady and Hagedorn, 1999b) suggests the response is not restricted to stellate cells, which are fewer in number and smaller in size than principal cells.

Irrespective of the cell type towards which kinin activity is directed, V_{tep} depolarizes due to the

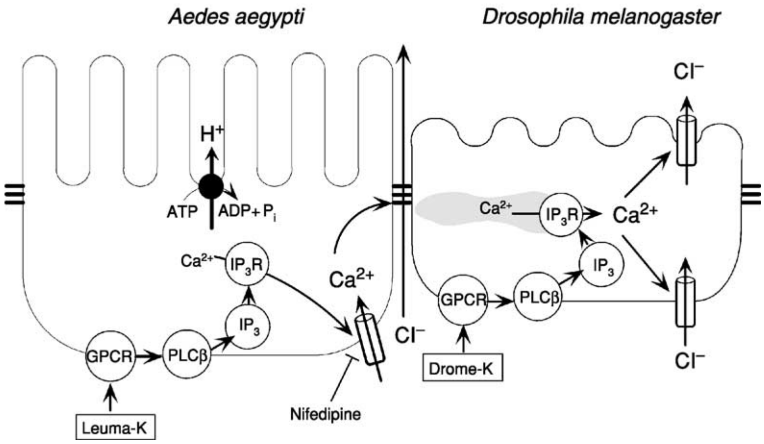

Figure 13 Kinin activity in Malpighian tubules of *Aedes aegypti* and *Drosophila melanogaster*. Kinins bind a PLCβ-coupled receptor and stimulate production of IP_3, which initiates Ca^{2+} release from endoplasmic reticulum IP_3 sensitive stores. The resultant increase in $[Ca^{2+}]_i$ opens a Cl^- selective shunt pathway that lies outside of the principal cells. Kinins (Leuma-K-8) act on *A. aegypti* principal cells, which have small IP_3 sensitive stores. Store emptying opens nifedipine sensitive store-operated Ca^{2+} channels (SOCC) in the basolateral membrane. Ca^{2+} entry through SOCC raises $[Ca^{2+}]_i$, which in some unknown way opens a paracellular conductance allowing Cl^- to diffuse into the lumen through intercellular septate junctions. In marked contrast, Drome-K binds a receptor (Drome-K-R) on the stellate cells of *D. melanogaster* tubules to stimulate production of IP_3. Release of Ca^{2+} from IP_3 sensitive stores elevates stellate cell $[Ca^{2+}]_i$, which opens a transcellular conductance pathway through Cl^- channels in the apical and basolateral membranes. GPCR, $G_{s\beta}$-coupled receptor.

opening of a Cl^- conductance pathway that lies outside of the principal cells. This pathway is believed to be through the stellate cells in fruit fly tubules because: (1) a high density of "maxi-Cl^-" channels are found in a small number of apical membrane patches, befitting the small number of stellate cells; and (2) vibrating probe analysis reveals Cl^- dependent current-density "hot spots" over stellate cells (O'Donnell *et al.*, 1998). Alternatively, Beyenbach's group argue that the Cl^- conductance pathway in *A. aegypti* tubules is paracellular through septate junctions (Wang *et al.*, 1996; Yu and Beyenbach, 2001); although Cl^- channels are present in the apical membrane of stellate cells, they are not maxi channels and are not activated by kinins (O'Connor and Beyenbach, 2001). Indeed, the work of Yu and Beyenbach, 2004 (see above) shows that stellate cells neither signal nor mediate the kinin response. The differences between kinin activity in *D. melanogaster* and *A. aegypti* have been viewed as somewhat controversial; nevertheless, these species have very different diets (blood versus fruit), which mandate different excretory demands. It seems probable that each is correct for that species. As noted earlier, Zdobnov *et al.* (2002) concluded that *D. melanogaster* and another mosquito, *A. gambiae*, are somewhat more divergent in evolution than the human and the pufferfish!

Malpighian tubules of the house cricket, *A. domesticus*, lack stellate cells, but respond to kinin stimulation with an increase in fluid secretion that is Cl^- dependent and probably mediated by a rise in $[Ca^{2+}]_i$ (Coast, 2001). As in dipteran tubules, kinins open a Cl^- conductance pathway causing V_{tep} to depolarize. Without stellate cells, this conductance can only be paracellular or through principal cells. The effects of ion substitutions in the bathing fluid on membrane potentials indicate that principal cells have a negligible basolateral Cl^- conductance both before and after kinin stimulation, which appears to rule out a transcellular pathway for Cl^- movement into the lumen (G.M. Coast, unpublished data). It is also worth noting that kinins have no effect on fluid secretion in *R. prolixus* tubules (Te Brugge *et al.*, 2002), which might be explained by the unusual lumen negative V_{tep} (Ianowski and O'Donnell, 2001) opposing passive diffusion of Cl^- through a paracellular conductance pathway.

3.10.3.12.3.1. Kinin receptors Recently, one of a group of putative neuropeptide receptors from *D. melanogaster* (Hewes and Taghert, 2001) has been identified as the probable receptor for Drome-K (Radford *et al.*, 2002). When heterologously expressed, the receptor shows an EC_{50} of 40 pmol l^{-1} and a t(1/2) <1 s for Ca^{2+} elevation. Earlier, Cox *et al.* (1997) cloned a receptor from a *Lymnaea stagnalis* (pond snail) cDNA library (see **Figure 14**), and also identified the endogenous kinin, lymnokinin (PSFHSWS-amide), in this same paper. When heterologously expressed in CHO cells, this receptor

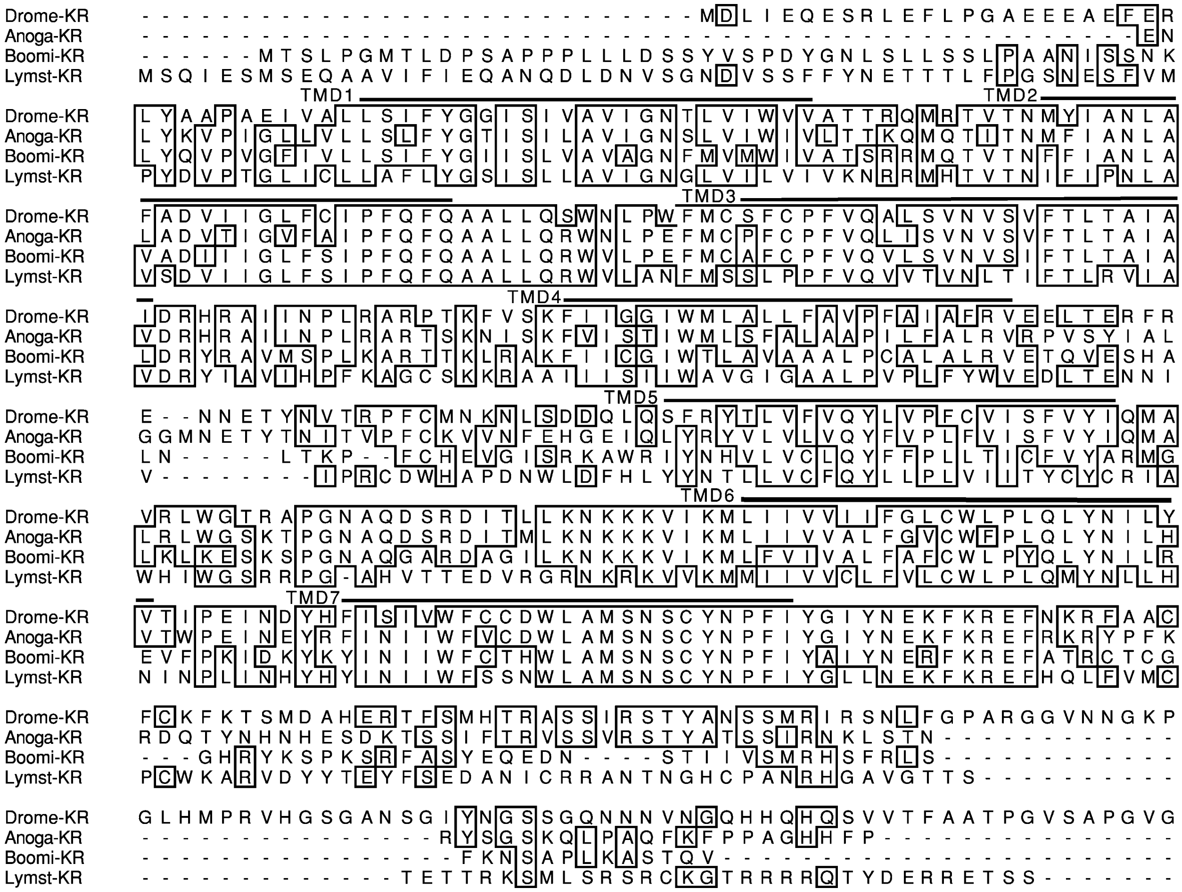

Figure 14 The kinin receptors (KR) are shown with identical residues boxed. Sequences were aligned with Clustal W, V. 1.8. The seven transmembrane domains (TMD) are indicated with a bold line and the domain number. Their approximate location was determined with the program TMHMM Server v. 2.0 at the Center for Biological Sequence Analysis, Technical University of Denmark (TMHMM, 2004). The bold lines were determined for the *Drosophila melanogaster* kinin receptor (Drome-KR); for the *Boophilus microplus* receptor (Boomi-KR) the location of TMD1, -2, -3, -4, -5, and -7 were identical with those of the Drome-KR, for TMD6 the domain started in the same place as the Drome-KR but ended 4 residues upstream. The final 70 C-terminal residues of Drome-KR are not shown for clarity. This receptor has an unusually long C-terminal intracellular domain.

was stimulated by lymnokinin with an EC_{50} for a Ca^{2+} response of 1.1 nmol l^{-1}. A "leucokinin-like" receptor has also been cloned from the cattle tick *Boophilus microplus* (Holmes *et al.*, 2000); it is clearly an ortholog to the above two kinin receptors. However, no ligand is known for this receptor in the tick, so no affinity data are available. In addition, an ortholog of these receptors occurs in the genome of *A. gambiae*.

3.10.3.12.4. CAP_{2b} family: cellular actions The diuretic activity of CAP_{2b} peptides has been most thoroughly investigated in fruit fly tubules in which they act through a Ca^{2+}-NO-cGMP signaling pathway to stimulate cation transport by increasing V-ATPase activity in principal cells, as evidenced by hyperpolarization of the transepithelial potential (V_{tep}) and acidification of the urine (O'Donnell *et al.*, 1996; Kean *et al.*, 2002). The binding of CAP_{2b} to a phospholipase C (PLCβ)-coupled receptor on principal cells in the main secretory segment stimulates the production of inositol (1,4,5)-trisphosphate (IP_3) which initiates the release of Ca^{2+} from endoplasmic reticulum IP_3-sensitive stores (see Figure 15 for model). In support of this, the tubules express genes encoding PLCβ (*norpA* and *plc21*) (Pollock *et al.*, 2003) and the IP_3 receptor (*itpr*) (Blumenthal, 2001), and the CAP_{2b}-stimulated diuresis is significantly reduced in tubules from *norpA* and *itpr* mutant flies (Pollock *et al.*, 2003). The amount of Ca^{2+} released from principal cell IP_3-sensitive stores is too small to be detected, but store emptying probably activates store-operated Ca^{2+} channels (SOCCs) and the influx of extracellular Ca^{2+}. This is essential for the CAP_{2b} stimulated diuresis, accounting for the relatively slow rise in $[Ca^{2+}]_i$. Fruit fly tubules express genes that encode a variety of Ca^{2+} channels involved in

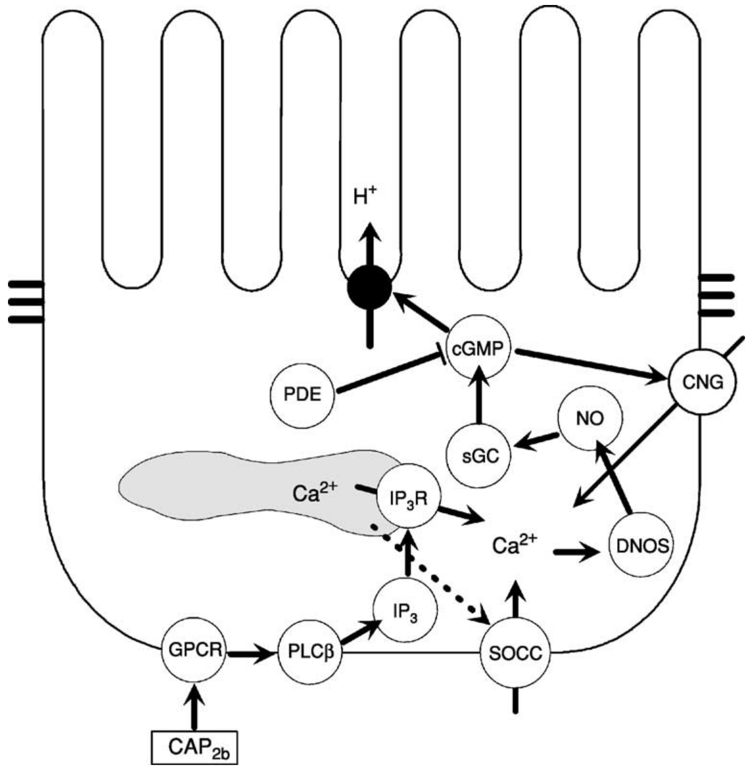

Figure 15 A model for the action of CAP_{2b} and orthologs via a nitridergic signaling pathway in *Drosophila melanogaster* principal cells. The binding of CAP_{2b} to a $G_{s\beta}$-coupled receptor (GPCR) stimulates production of IP_3, which initiates Ca^{2+} release from endoplasmic reticulum stores by opening ligand gated Ca^{2+} channels (IP_3R). Emptying of these IP_3 sensitive stores activates store-operated Ca^{2+} channels (SOCC) and the resultant rise in $[Ca^{2+}]_i$ stimulates a Ca^{2+}-calmodulin nitric oxide synthase (*Drosophila* NOS, or DNOS) and elevates nitric oxide (NO) production. NO activates a soluble guanylate cyclase (sGC), increasing production of cGMP, which activates the apical membrane V-ATPase. Cyclic GMP also opens cyclic nucleotide gated Ca^{2+} channels (CNG) in the basolateral membrane, which augments the Ca^{2+}signal. The hydrolysis of cGMP by phosphodiesterase (PDE) appears to be important in modulating the stimulation of fluid secretion by CAP_{2b}.

Ca^{2+} transport and signaling. These include the genes *trp* and *trpl* that encode Trp and Trp-like (Trpl) channel proteins. Analysis of *trp* and *trpl* mutants implicates TRPL in the diuretic response to CAP_{2b} and this could therefore be the elusive SOCC. The CAP_{2b} stimulated rise in $[Ca^{2+}]_i$ is sufficient to activate nitric oxide synthase, which is a Ca^{2+}/calmodulin sensitive *D. melanogaster* nitric oxide synthase (NOS) that is expressed only in principal cells (Davies *et al*., 1997; Rosay *et al*., 1997; Davies, 2000). The NO generated by NOS activates a soluble guanylate cyclase (sGC) resulting in elevated levels of cGMP, which are confined to the principal cells (Kean *et al*., 2002). Interestingly, fruit fly tubules express a gene encoding a cyclic nucleotide gated channel (CNG), and activation of this channel by cGMP may contribute to the influx of extracellular Ca^{2+} and help sustain the rise in $[Ca^{2+}]_i$ (MacPherson *et al*., 2001). Other possible targets for the cGMP produced in response to CAP_{2b} stimulation include cGMP dependent protein kinases (cGKs), and two genes encoding cGK (*dg1* and *dg2*) are expressed in tubules. Significantly, tubules from *dg2* mutant flies are hypersensitive to cGMP, and the cGK could therefore be involved in activating the apical V-ATPase, the ultimate target of CAP_{2b} (Dow and Davies, 2003).

The detailed dissection of the elaborate signal transduction pathway for CAP_{2b} in fruit fly tubules is testament to the advantages afforded by the powerful combination of molecular biology and genetic analysis in unravelling complex physiological processes. Nevertheless, it is important to remember that however elegant a model, it provides only a description of what occurs in the fruit fly and may be quite different in other insects. Indeed, when CAP_{2b} peptides have been tested in other species their actions differ from those described in the fruit fly. For example, CAP_{2b} stimulates fluid secretion by housefly (*M. domestica*) tubules by a NO-cGMP independent mechanism that results in V_{tep} depolarizing rather than hyperpolarizing and is not accompanied by urine acidification (C.S. Garside and G.M. Coast, unpublished data). The cellular actions

of CAP_{2b} in the housefly are very similar to those of the kinins in that the depolarization of V_{tep} is due to the opening of a Cl^- conductance pathway that lies outside of the principal cells and may be paracellular or transcellular through the stellate cells (see above in this section). Moreover, CAP_{2b} activity is not dependent on Ca^{2+} influx from the bathing medium, but most likely involves Ca^{2+} release from intracellular stores, because prior treatment of tubules with thapsigargin blocks CAP_{2b} stimulated diuresis. If housefly principal cells have only small stores of releasable Ca^{2+}, as in fruit fly tubules, then the assumption is that CAP_{2b} acts on stellate cells. In this context, it is noteworthy that high concentrations (100 nmol l^{-1}) of CAP_{2b} peptides increase $[Ca^{2+}]_i$ in the stellate cells of fruit fly tubules (Kean *et al.*, 2002). The response to Drome-capa-1 is large enough to open the stellate cell Cl^- conductance and, in combination with the stimulation of active cation transport by the principal cells, this might explain the more potent diuretic activity of this peptide compared with Drome-capa-2 and Manse-CAP_{2b}.

In contrast to the diuretic activity of CAP_{2b} peptides in the housefly and fruit fly, CAP_{2b} acts via cGMP to reduce secretion by MT from *R. prolixus* and *T. molitor* larvae, and *A. aegypti* adult females. CAP_{2b} (and cGMP) antagonizes the actions of cAMP and the diuretic hormones serotonin (*R. prolixus*; Quinlan *et al.*, 1997) and Tenmo-DH_{37} (*T. molitor*; Wiehart *et al.*, 2002), both of which act via cAMP dependent mechanisms to stimulate tubule fluid secretion. The antagonist effects of CAP_{2b} and cGMP can be explained by the activation of a cGMP dependent cAMP phosphodiesterase (Quinlan *et al.*, 1997), which would lower intracellular levels of cAMP and thus reduce tubule secretion.

3.10.3.12.5. Cellular actions of antidiuretic factors inhibiting Malpighian tubule secretion The first insect neuropeptide shown to inhibit MT secretion was Manse-CAP_{2b}, first isolated as a myotropin from *M. sexta*. This peptide has no effect on MT of the species from which it was isolated (Skaer *et al.*, 2002). However, Quinlan *et al.* (1997) reported CAP_{2b} to be antidiuretic in *R. prolixus*, and that low levels of cGMP or Manse-CAP_{2b} would decrease the serotonin stimulated secretion of MT. These effects could be reversed by addition of 1 mmol l^{-1} cAMP. Subsequently, they studied further the antagonistic effects of cGMP and cAMP on *R. prolixus* MT; an inhibitory level of cGMP was without effect on the concentrations of K^+ and Na^+ of secreted fluid (Quinlan and O'Donnell, 1998). Transport of organic anions into upper tubules involves at least two different transporters: one for acylamides (e.g., *p*-aminohippuric acid) and another for sulfonates (e.g., amaranth and phenol red). Amaranth and phenol red blocked the actions of both cGMP and cAMP, whereas *p*-aminohippuric acid was without effect, suggesting that exogenous cyclic nucleotides are carried into the MT cell by the sulfonate transporter (Quinlan and O'Donnell, 1998). These workers hypothesized that cGMP activated a cAMP phosphodiesterase, but have apparently not provided any proof for this.

In *T. molitor*, both CAP_{2b} and the two *T. molitor* antidiuretics, ADFa and ADFb, act by stimulating a guanylate cyclase, probably membrane bound. As found in *R. prolixus*, Wiehart *et al.* (2002) showed that ADFa and Tenmo-DH_{37} have antagonistic effects, the former elevating cGMP levels and the latter elevating cAMP levels. It also seems likely in this species that cGMP activates a cAMP specific phosphodiesterase. Attempts to prove this by using *T. molitor* MT incubated with 1 μmol l^{-1} erythro-9-(2-Hydroxy-3-nonyl)adenine. HCl (EHNA), a selective inhibitor of the cGMP activated cAMP phosphodiesterase II (Podzuweit *et al.*, 1995), and 100 fmol l^{-1} Tenmo-ADFa were unfortunately inconclusive (S.W. Nicolson, R.J. Eigenheer, and D.A. Schooley, unpublished data).

Tenmo-ADFa has been recently found to have antidiuretic action in *A. aegypti*; at 1 nmol l^{-1} concentrations in a Ramsay assay it significantly inhibited the rate of fluid secretion without significant effects on the concentrations of Na^+, K^+, and Cl^- in secreted fluid and also significantly increased intracellular cGMP concentration, consistent with a second messenger role (Massaro *et al.*, 2004). Low doses of cGMP (20 μmol l^{-1}) inhibit isosmotic fluid secretion without inducing electrophysiological effects, whereas cGMP at 500 μmol l^{-1} significantly depolarized the basolateral membrane, but hyperpolarized the transepithelial potential. Low concentrations of Tenmo-ADFa and cGMP inhibit isosmotic fluid secretion by reducing electroneutral transport, whereas high levels of cGMP increase an unknown conductance of the basolateral membrane and depolarize the basolateral membrane voltage supplemental to and independent of the electroneutral mechanism of action of low concentrations of cGMP (Massaro *et al.*, 2004).

While CAP_{2b} has been termed an "antidiuretic hormone" in *R. prolixus* (O'Donnell and Spring, 2000), this may be premature: in *T. molitor*, only two zones of material that elevated cGMP levels in MT were isolated and sequenced, even though ADFb (Eigenheer *et al.*, 2003) is 24 000 times less potent than ADFa (Eigenheer *et al.*, 2002). CAP_{2b}

($EC_{50} = 85\,nmol\,l^{-1}$) is less potent still than ADFb; the presence of CAP_{2b} or a paralog in *T. molitor* would probably have been detected. It is quite interesting that cGMP has so far been found to be antidiuretic in two phylogenetically disparate blood feeders, *R. prolixus* and *A. aegypti*, and a starkly xeric species, *T. molitor.* Quinlan and O'Donnell (1997) have argued that an antidiuretic factor could be of great importance in a blood feeder to cause a rapid decrease in postblood meal diuresis, in order to avoid depleting the hemolymph volume. In fact, they observed that day 2 postblood meal MT were far more sensitive to the effects of CAP_{2b} than day 12 MT, with day 22 postblood meal MT still less sensitive. *Tenebrio molitor* is so highly evolved for water absorption that activities of K^+ in its cryptonephric MT exceeding 3 M have been measured (O'Donnell and Machin, 1991), allowing absorption of water vapor from the rectum above 88% relative humidity. (Despite this species having high hemolymph Na^+, the active transport mechanism in MT is quite selective for K^+.) Thus, antidiuretic factors could be quite important in conserving water in this species.

It seems surprising that cGMP has been found to have the opposite effect, diuresis, in *D. melanogaster* (Davies *et al*., 1995) and *M. sexta* (Skaer *et al*., 2002). However, cGMP is only weakly diuretic in the dipteran *M. domestica*, and Drome-capa-2 (one of three endogenous Manse-CAP_{2b}-like peptides encoded by the *D. melanogaster* genome) is diuretic with actions that resemble those of Musdo-K (G.M. Coast, unpublished data). It is possible that the diuretic effect of cGMP in certain species may be due to stimulation of a cGMP stimulates cAMP phosphodiesterase (PDE type III).

3.10.3.12.6. Cellular actions of ITP: an antidiuretic factor that promotes fluid reabsorption in the hindgut Schgr-ITP acts via cAMP to stimulate salt (NaCl/KCl) and water uptake from the locust ileum (Phillips *et al*., 1998b). Its actions have been studied extensively in flat sheet preparations of the locust ileum mounted between two Ussing chambers (this method is suitable only for large insects, even the hindgut of adult *M. sexta* is too small (S. Liao, J. Kenyon, and D.A. Schooley, unpublished data)). Addition of Schgr-ITP or cAMP to the hemolymph side results in a ten-fold stimulation of the current (short circuit current; I_{scc}) needed to clamp the tissue at a transepithelial potential (V_{tep}) of 0 mV. The ITP stimulated I_{scc} is Cl^- dependent and reflects a ten-fold increase in net active Cl^- transport from the luminal to the basal surface of the epithelium against an overall electrochemical potential gradient (see Figure 16 for model). Extensive

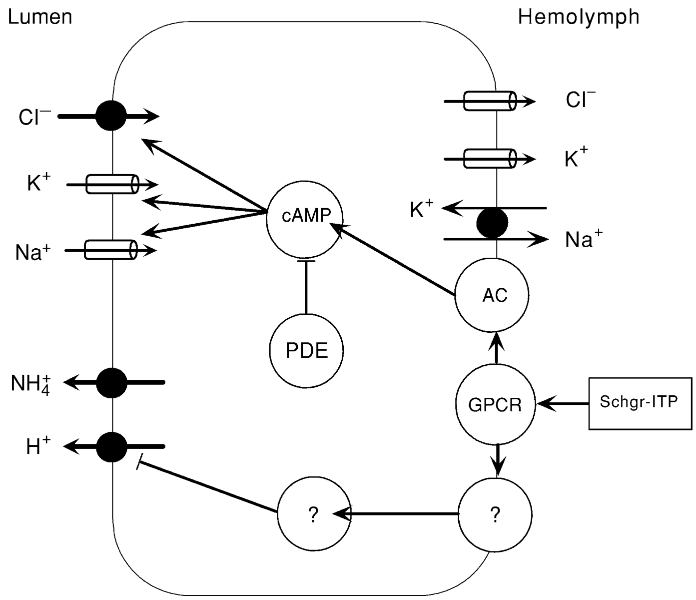

Figure 16 Proposed actions of Schgr-ITP on ion transport by locust ileum. Schgr-ITP stimulates ion transport and isosmotic fluid reabsorption from the lumen of the ileum. Acting via cAMP, it stimulates the apical electrogenic Cl^- pump, which is the prime driving force for ion and fluid transport. Cyclic AMP, also opens conductance pathways for Na^+ and K^+ in the apical membrane. K^+ and Cl^- exit to the hemolymph side of the epithelium through conductance pathways in the basolateral membrane, while Na^+ is removed via Na^+-K^+-ATPase activity. Schgr-ITP also inhibits ileal acid (H^+) secretion via a cAMP independent pathway. AC, adenylate cyclase; PDE, phosphodiesterase; GPCR, $G_{s\alpha}$-coupled receptor.

electrophysiological studies reveal that the active transport step takes place at the apical (luminal) membrane and involves an unusual (for vertebrates) electrogenic Cl^- pump that is stimulated by cAMP (Phillips *et al.*, 1998b). Chloride exits the cells to the hemolymph side by passive diffusion through a large basolateral membrane Cl^- conductance. The major cations (Na^+ and K^+) follow Cl^- passively across the apical membrane through separate conductance pathways both of which are increased by cAMP. At the hemolymph side, K^+ exits the cells passively via a large K^+ conductance in the basolateral membrane, whereas Na^+ is actively removed from the cells by a Na^+–K^+–ATPase pump. Fluid uptake from the locust ileum is driven by active salt (NaCl/KCl) transport and isosmotic fluid reabsorption is stimulated fourfold by Schgr-ITP and cAMP (Phillips *et al.*, 1998b). Interestingly, while both Schgr-ITP and crude extracts of corpora cardiaca inhibit active acid (H^+) secretion into the lumen of the ileum, cAMP is without effect indicating the involvement of another second messenger in the actions of this peptide (Phillips *et al.*, 1998a).

Schgr-ITP has been shown to have no effect on secretion of MT from *S. gregaria* (Coast *et al.*, 1999); similarly, Locmi-K and Locmi-DH have no effect on the ilea or recta of *S. gregaria in vitro*. Locmi-K and Locmi-DH have a synergistic effect on MT of *S. gregaria*, and this effect is much faster than the effect of Schgr-ITP on the ileum. These data would suggest that in early phases of feeding, urine secretion would commence before reabsorption, allowing voiding of excess water (Coast *et al.*, 1999).

3.10.3.12.7. The cryptonephric complex and cellular actions of factors acting on it The cryptonephric complex of Coleoptera and larval Lepidoptera is a composite tissue consisting of both excretory and reabsorptive tissue. In this anatomy, which differs between the two orders, the rectum is closely associated with the distal part of the MTs, which lie within a perinephric space that is separated from the hemolymph by a water impermeable perinephric membrane. The cryptonephric tubules of *T. molitor* contact the perinephric membrane at regions called "boursouflures" (or "bulges"). Here the perinephric membrane is greatly reduced and forms a "blister" over an underlying leptophragma cell (Ramsay, 1964). Ramsay postulated that KCl is transported from the hemolymph into the cryptonephric tubules across the leptophragma cells without an accompanying movement of water, thereby establishing a high osmotic concentration (as much as 6.8 Osm in *T. molitor* larvae, close to water-saturation for KCl) in the tubule lumen (O'Donnell and Machin, 1991). The perinephric space also has a high osmolarity consisting largely of nonionic solutes (melting point depression up to $-10\,°C$) with a Na^+–K^+ ratio similar to that of hemolymph (Ramsay, 1964), unlike the distal parts of the cryptonephric tubules, which absorb K^+ to the near exclusion of Na^+ (O'Donnell and Machin, 1991). Using double-barrel microelectrodes and dye injections, O'Donnell and Machin (1991) also found that the perinephric space is an important functional part of the cryptonephric complex. They reported large pH (as much as 2 units, averaging 1.1 units) and electrochemical gradients (70 mV) across the apical membrane of the tubule, with the average K^+ activity across the membrane exceeding the Nernst equilibrium by 75-fold. They favor a model where cations enter the perinephric space through the anterior, more permeable part of the perinephric sheath. Anions may enter the perinephric space separately, possibly through the leptophragma cells, present in the *T. molitor* cryptonephric complex but absent from *M. sexta*. This could be consistent with the leptophragma cells being equivalent to stellate cells in other species. The highest activity of K^+ measured in their studies was apparently near the distal end of the cryptonephric MT. The high osmotic concentration in the tubule accounts for the osmotic withdrawal of water from first the perinephric space and ultimately the rectal lumen. This exceptional osmotic gradient may be necessary to drive water transport across at least two membranes and can account for the uptake of water vapor from air of >89% relative humidity (RH) (Coutchié and Machin, 1984). A very recent paper describes a microcalorimetric study on larvae of *T. molitor* exposed to a dry atmosphere; there was a doubling of metabolic activity prior to commencement of water vapor absorption from the air (Hansen *et al.*, 2004), which could indicate hormonal involvement in this metabolic activity. The consequence of this anatomy is that DH (at least CRF-like DH) promote salt uptake from the hemolymph, but water uptake from the rectum. In fact, Ramsay(1964) hypothesized that the cryptonephric complex in beetles evolved to conserve water. Nicolson (1991) speculated that a DH in similar Coleoptera might serve as a clearance hormone rather than a diuretic hormone, with the fluid flow directed into the midgut to moisten the dry food for digestion, and the fluid reabsorbed in the midgut. This model raises the question of where reabsorption of electrolytes, at least other than KCl, from the hindgut occurs in these species. It is clear that the model developed for fluid reabsorption in locusts is not

applicable for Coleoptera given the cryptonephric anatomy.

The cryptonephric complex of lepidopteran larvae differs significantly from that of *T. molitor* in that it is restricted to three longitudinal bands running the length of the rectum, corresponding to the three pairs of MTs (Ramsay, 1976). Between each band, a patch of "normal" rectal epithelium separates the luminal contents from the hemocoel. Additionally, boursouflures appear to be absent in the lepidopteran cryptonephric complex, which nevertheless is assumed to function in a manner similar to that of *T. molitor*, although high osmotic concentrations are not established. Ramsay (1976) argued that the cryptonephric complex in Lepidoptera evolved to handle the osmotic challenge of ingesting massive quantities of salt, because he found that *M. sexta* larvae were able to feed on a diet containing sufficient NaCl to represent 1 kg of salt per day for an adult human! However, most lepidopterans feed on plants with high K^+ and low Na^+. Ramsay did not test KCl; perhaps this ability to excrete high Na^+ is more linked to the high hemolymph K^+ content of this species (Sutcliffe, 1963). About 90% of the fluid entering the rectum of day 1 fifth instar larvae is reabsorbed (Reynolds and Bellward, 1989), a quarter of which enters the cryptonephric tubules and is recycled to the midgut via the straight ascending and descending tubule segments (Moffett, 1994). At the same time, K^+ in the tubule lumen is returned to the midgut in exchange for Na^+ (Moffett, 1994). The remaining fluid is reabsorbed across the "normal" epithelium, which is composed of cells with extensive infoldings of the apical and basolateral membranes and associated mitochondria (Reynolds and Bellward, 1989). The latter group argued that the ileum of *M. sexta* has no ultrastructural characteristics of a reabsorptive tissue, suggesting that fluid reabsorption in this species is dependent on the "normal" rectal epithelium.

Audsley *et al.* (1993) presented evidence that Manse-DH has a net antidiuretic effect on the cryptonephric complex of *M. sexta*. They showed that Manse-DH stimulates a bumetanide sensitive Na^+–K^+–$2Cl^-$ cotransporter, causing an influx of salt from the hemolymph, with fluid following from the rectal lumen. Transport processes that are consistent with their findings are summarized in **Figure 17**. Crucial to this work was development of an assay using everted rectal sacs from fifth instar larvae. In this preparation, the rectal lumen is on the outside, while the hemolymph side of the tissue is sealed around a polypropylene tube so that reabsorption into the hemolymph is manifest by a weight gain over time. Further details of the preparation are given by Liao *et al.* (2000), who used it to demonstrate the existence of two factors in CC–CA of larval *M. sexta* that are distinct from Manse-DH and trigger fluid reabsorption by the cryptonephric complex of this species (see above in this section). The more abundant of these two factors, Manse-ADF-B = Manse-ADF-2, is believed to stimulate a Cl^--ATPase via cAMP as second messenger, a mechanism of action apparently identical to that of Schgr-ITP. Elucidating the mechanism of action of Manse-ADF-2 could only be accomplished via use of selective inhibitors, because Manse-DH also exerts its antidiuretic effect on the tubules via cAMP. However, incubation of everted rectal sacs with bafilomycin A_1 (an inhibitor of the V-ATPase) on the hemolymph side of the tissue was found to block the basal reabsorption by this tissue, masking the effect of Manse-DH, as does incubation with the far cheaper amiloride on the lumen side, an inhibitor of the H^+-alkali metal antiporter. Addition of Manse-ADF-2 to these inhibited preparations caused a highly significant increase in fluid reabsorption; the reabsorption was easier to measure in the presence of the inhibitors due to the strong decrease in basal reabsorption. Incubation of rectal sacs with H-89, a potent and selective inhibitor of protein kinase A, blocks the effect of Manse-ADF-2. In addition, incubation of rectal sacs with the Cl^- channel blockers DIDS or DPC caused a significant decrease in reabsorption, and the reabsorption could not be relieved by treatment with Manse-ADF-2. The ionic transport believed to occur in the "normal" rectal epithelium as a result of this antidiuretic factor is summarized in **Figure 17**.

In examining the alignment (**Figure 5**) of the 15 known CRF-like DHs, the sequences from two lepidopteran species and one beetle species differ significantly from those of other species, as reflected by the fact that this Clustal W alignment ranks them differently from the other sequences (phylogenetically, Tenmo-DH_{47} is aligned between Achdo-DP and Manse-DPII, but for this figure it was moved up next to the lepidopteran sequences). It is tempting to hypothesize that the divergence of these sequences from the other CRF-like DHs may have to do with the existence of the cryptonephric complex in larvae of *M. sexta* and larvae and adults of *T. molitor.*

3.10.3.13. Synergism

In general, the transport of cations (K^+ and Na^+) and anions (Cl^-) by Malpighian tubules appears to be regulated separately (O'Donnell *et al.*, 1996). Thus, depending on species, CRF-related, CT-like,

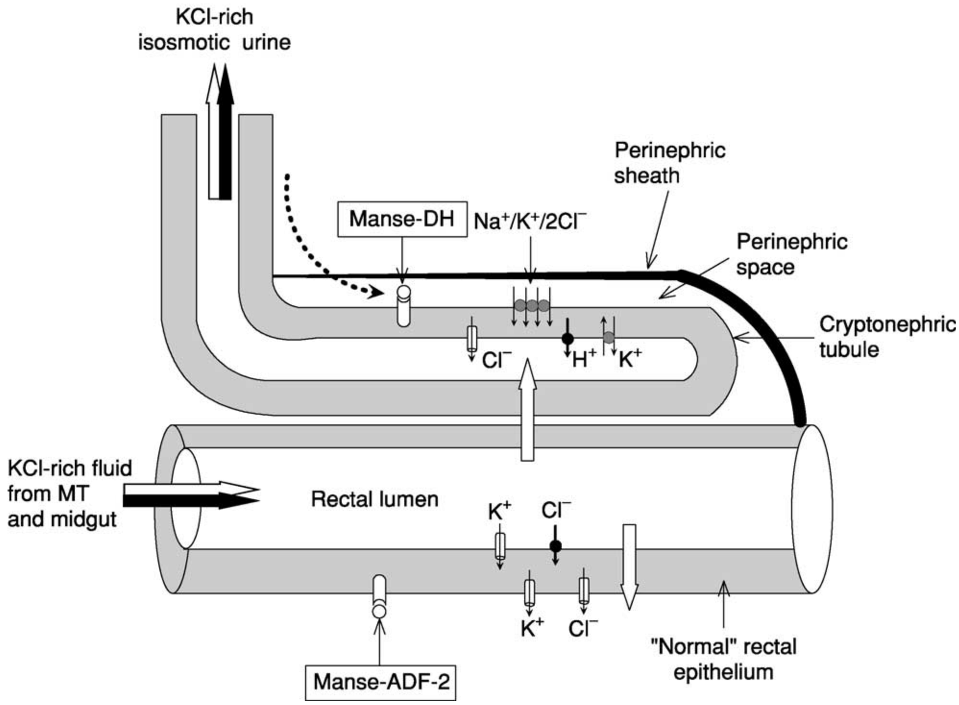

Figure 17 A model for the hindgut of *Manduca sexta* and similar lepidopteran larvae. At the top is shown one of three longitudinal segments of cryptonephric complex; on the opposing side of the hindgut lies a longitudinal segment of ''normal'' rectal epithelium. There are three radially symmetrical bands of cryptonephric tubules and ''normal'' rectal epithelium. Fluid entering the rectal lumen from the midgut and Malpighian tubules is reabsorbed by the cryptonephric tubules (CNT) and by the ''normal'' epithelium. The CNT lie in a perinephric space (PNS) isolated from the hemolymph by a water impermeable perinephric membrane (PNM). Ion transport by CNT is similar to that described in principal cells, with cation uptake from the PNS occurring via Na^{+}-K^{+}-$2Cl^{-}$ cotransport. Manse-DH acts via cAMP to stimulate the cotransporter and hence increase secretion of KCl-rich fluid into the CNT lumen. The withdrawal of water from the PNS creates an osmotic gradient favoring the passive withdrawal of water from the rectal lumen. Ions may enter the PNS from the rectal lumen (not shown) or across a thinner and more permeable (to ions) anterior region of the PNM (dotted arrow). In contrast to the actions of Manse-DH, Manse-ADF-2 acts via cAMP to stimulate ion transport and hence fluid reabsorption across the ''normal'' rectal epithelium. Ion transport by the rectal epithelium appears to be driven by an apical electrogenic Cl^{-} pump (c.f. the locust ileum) that is stimulated by cAMP. Cl^{-} exits the cells by passive diffusion through Cl^{-} channels in the basolateral membrane. The active transport of Cl^{-} from lumen to hemocoel establishes a favorable gradient for passive reabsorption of K^{+} through conductance pathways in the apical and basolateral membranes.

and CAP_{2b} peptides (*D. melanogaster*) stimulate active cation transport, whereas kinins and CAP_{2b} peptides (*M. domestica*) open a Cl^{-} selective shunt pathway to increase anion movement into the tubule lumen. By stimulating different transport processes, either through different second messengers or by acting on different cell types, combinations of these diuretics can have an effect on tubule fluid secretion that is greater than the sum of their separate effects. An electrophysiological basis for this synergism can be derived from an electrical equivalent circuit used to model transepithelial ion transport (Clark *et al.*, 1998a) (**Figure 18**). The circuit comprises elements representing the active transport pathway for K^{+} and Na^{+} through the principal cells, in parallel with a passive transport pathway for Cl^{-} that lies outside of the principal cells. Within the active pathway, E_{cell} and R_{cell} represent the electromotive force and the resistance to cation transport, respectively, whereas R_{shunt} defines the passive transport pathway. The two pathways are coupled on the apical and basal sides of the epithelium by the conductances of the urine and hemolymph, respectively. It follows that any increase in ion transport through one pathway must be matched by equivalent movement through the other pathway to maintain electrical neutrality. The current flow through the circuit (I_{loop}) is described by Ohm's law, where $I_{loop} = E_{cell}/R_t$, with R_t being the transepithelial resistance ($R_t = R_{cell}R_{shunt}/(R_{cell} + R_{shunt})$). Reducing either R_{cell} or R_{shunt} will increase transepithelial ion secretion as evidenced by the increase in I_{loop}. However, a reduction in both R_{cell} and R_{shunt} will increase ion secretion (I_{loop}) by far more than the sum of their separate effects (Clark *et al.*, 1998a). Such synergistic control of tubule secretion has been demonstrated in tubules of *L. migratoria* (Coast, 1995) and *M. domestica*

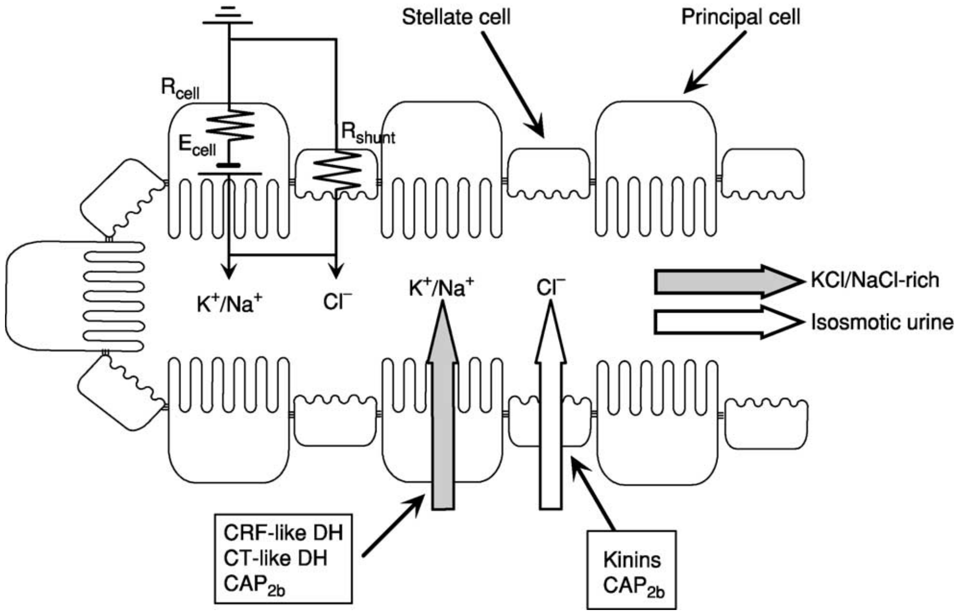

Figure 18 An electrical equivalent circuit model for the secretion of KCl and/or NaCl by Malpighian tubules. The circuit comprises parallel active cation (K^+ and Na^+) and passive anion (Cl^-) transport pathways, the former through principal cells and the latter through either stellate cells or intercellular junctions (not shown). E_{cell} is the electromotive force of the active pathway and is primarily generated by the apical membrane V-ATPase. R_{cell} is the transcellular resistance to active transport, while R_{shunt} is the resistance of the anion pathway to the diffusion of Cl^- into the lumen. Current flow (the equivalent of ion transport) through the separate pathways must be equal in order to preserve electrical neutrality. Synergism between factors that separately stimulate cation and anion transport can in part be explained by the combined effect of reducing R_{cell} and R_{shunt} on intraepithelial current flow, which is greater than the sum of their single effects. (Adapted with permission from Clark, T.M., Hayes, T.K., Beyenbach, K.W., **1998a**. Dose-dependent effects of CRF-like diuretic peptide on transcellular and paracellular transport pathways. *Am. J. Physiol. Renal Physiol. 274*, F834–F840.)

(Iaboni *et al*., 1998) challenged with a combination of their CRF related peptides and kinins to stimulate cation and anion transport, respectively. Interestingly, the CRF related peptide (Dippu-DH_{46}) and CT-like peptide (Dippu-DH_{31}) act synergistically to stimulate secretion by *D. punctata* tubules, although in this instance the peptides appear to use the same second messenger, namely cAMP (Furuya *et al*., 2000b). A possible explanation is that the peptides act on different cell types as seen in fruit fly tubules with the segregation of Ca^{2+} signaling pathways stimulated by CAP_{2b} (principal cells) and Drome-K (stellate cells) (Rosay *et al*., 1997). Synergism has also been demonstrated between serotonin and a peptide diuretic hormone from the mesothoracic ganglion mass of *R. prolixus* (Maddrell *et al*., 1993a). The peptide is unlikely to be a CRF related DH, but may be a CT-like peptide (V. Te Brugge and I. Orchard, unpublished data). Its mode of action will be of some interest, because serotonin itself stimulates both cation and anion transport in *R. prolixus* tubules (Ianowski and O'Donnell, 2001).

Synergism between two (or more?) diuretics offers a number of advantages arising from the fact that less hormone needs to be released into the circulation to stimulate diuresis. For example, diuresis can be turned on and off more rapidly, because there is less hormone to inactivate, and there will be energy savings in terms of the cost of hormone synthesis. The steeper dose–response curve that characterizes synergism (Maddrell *et al*., 1993a; Coast, 1995) means that a small change in hormone concentration can have a pronounced impact on fluid secretion, resulting in more precise control of diuresis and it is noteworthy that Locmi-DH and Locmi-K, which are co-localized in abdominal ganglion neurosecretory cells (Patel *et al*., 1994), are not co-localized in the brain and corpora cardiaca. This requires that hormone release be coordinated and it is significant that the receptor for Drome-K (Drome-K-R) is present on neurosecretory cells in the pars intercerebralis that express Drome-DH, and in their axons in the retrocerebral complex (Radford *et al*., 2002).

3.10.3.14. Possible Utility of Research on Hormonal Control of Fluid Homeostasis

There is a long-term practical significance to this research. Over 30 years ago a *Nature* paper reported that insects poisoned with conventional insecticides were found to have undergone a profound diuresis, which probably contributed to their death (Maddrell

and Casida, 1971). Control of fluid homeostasis has long been recognized as a point of great vulnerability of the Insecta, because for most species all water ingested comes from the diet. Discovery of low molecular weight agonists or antagonists of diuretic or antidiuretic hormones could lead to a new class of safe, insect specific pesticides. Screening for such molecules will be possible with the implementation of rapid, simple receptor binding assays for important classes of neuropeptides crucial in controlling water balance. Such an assay has been described for the tachykinin receptor by Torfs *et al.* (2002), who engineered *D. melanogaster* S2 cells to express recombinant aequorin together with the tachykinin receptor, and also for the Drome-K receptor using the identical approach by Radford *et al.* (2002). Agents binding to this receptor, in particular agonists, trigger an easily measured bioluminescent response suitable for high-throughput screening. Such research is one of the major thrusts of pharmaceutical companies seeking to develop new drugs. Two classes of insecticides with hormonal activity are known: (1) juvenoids, agonists of the sesquiterpenoid juvenile hormones, are useful for controlling many insects where the adult is the pest; (2) ecdysone agonists, such as tefubenozide, or MIMIC®, are useful for control of even larval stages of insects. One of the chief liabilities of these chemicals is that they work by altering gene transcription, and so are slow acting. Peptide hormone mimics should work within seconds to minutes, surmounting one of the principal shortcomings of prior hormonal pesticides.

Acknowledgments

F. Horodyski thanks the National Science Foundation (IBN-9807907) for financial support. D. Schooley and G. Coast thank the National Institutes of Health (GM-48172-11) for financial support. We also thank numerous colleagues (Drs C. Garside, E. Lehmberg, K. Schegg, R. Eigenheer, S. Nicolson, S. Liao, J. Kenyon, V. Te Brugge, and I. Orchard, as well as Ms. E. Chidembo and P. Dey) for allowing us to cite unpublished data. D. Schooley would like to thank his wife Eleanor and his editor Larry for their patience.

3.11 Circadian Organization of the Endocrine System

X Vafopoulou and C G H Steel, York University, Toronto, ON, Canada

3.11.1. Introduction

The subject of this chapter has not been reviewed previously. In the 1985 edition of *Comprehensive Insect Physiology, Biochemistry, and Pharmacology*, circadian biology (Page, 1985) was not included in the two volumes on endocrinology. This fact illustrates the enormous extent of the changes in both fields that have taken place since that time.

Since 1985, endocrinologists have encountered increasingly complex patterns of regulatory interactions among insect hormones, the dissection of which has revealed circadian rhythms in the synthesis and hemolymph titer of numerous hormones. The quest to decipher the functional significance of these phenomena has drawn endocrinologists into the relatively unfamiliar territory of circadian biology (discussed by Steel and Vafopoulou, 2002). From this quest, a new level of understanding of the roles of hormones is emerging. Once regarded as agents that pulled switches that would activate or inhibit certain processes, hormones are increasingly recognized as agents that convey information about time (of day) to diverse cells and tissues that lack other access to such temporal information. Target cells use this information to organize their cellular activities into temporal sequences. Such internal temporal organization is a prerequisite for life; organisms maintained in continuous light (LL) often fail to develop or reproduce, or else die prematurely (Pittendrigh, 1993). In addition, rhythms in hormones expose target cells throughout the insect to the same temporal information simultaneously, creating synchronization of the activities of cells in otherwise unconnected anatomical locations. These circadian rhythms are propelled by specialized regions of the insect (often, but not always, in the nervous system) known as circadian clocks, which endogenously generate rhythms of roughly 24 h periodicity and transmit this rhythmicity to other cells, primarily via nerves or hormones. Until 10 years ago, these clocks could be localized only by crude methods such as lesioning areas of tissue, which precluded analysis of both the cellular mechanism of timekeeping and its relationships with the endocrine system.

Even more profound revolutions have occurred since 1985 in the field of circadian biology. A comprehensive survey is given by Saunders (2002). A number of genes has been cloned, initially from *Drosophila melanogaster,* which seem to have no role other than to participate in molecular oscillations that generate circadian rhythms (see **Chapter 4.11**). These genes are known as clock genes, of which *period* (*per*) and *timeless* (*tim*) are the best known. These molecular oscillators appear to be functional only in a limited number of groups of

cells in the insect. The ease with which clock gene transcripts and their proteins can be detected and quantified has resulted in the localization of circadian clocks to identified cells and in the discovery of many novel loci of circadian clock gene expression. Thus, endocrinologists (among others) have been given a powerful set of new tools with which to unravel the relations between circadian clocks and the endocrine system.

The confluence of endocrinology and circadian biology is especially clear in the mechanisms that regulate development and reproduction. Both of these processes involve intricate hormonal controls and both are intimately linked with environmental signals that govern their timing. The nature, significance, and implications of clock control over these sets of hormones comprise the bulk of this chapter. This is relatively a new subject and leaves greater room for speculation and suggestions for future research than the reader may encounter in other chapters in this volume. The confluence of the two fields is most visible at the cellular level, where recent evidence reveals the close physical association between clock cells and endocrine cells in several anatomical locations. But hormones are not only the controlled output of clocks; several hormones are now known to act on clocks, where they regulate critical features of rhythmicity such as phase. Such findings are leading to the recognition that hormones also function to couple circadian clocks together, so that they function as a coordinated timing system which orchestrates the myriad events that occur in an insect every day.

3.11.2. Clocks and Oscillators: An Introduction for Endocrinologists

The later sections of this chapter describe evidence of the presence of circadian clocks and oscillators in numerous organs and tissues in insects. A variety of different methods has been employed to obtain this evidence. Therefore, it is important to keep in mind the virtues and limitations of the various methods. These are discussed briefly here. Definitive proof that particular cells comprise a circadian clock cannot be derived from any one of these alone, a combination of approaches being needed. The most convincingly documented clocks, such as the optic lobe clock that controls the locomotor rhythm (Page, 1985; Helfrich-Förster *et al.*, 1998; Helfrich-Förster, 2003), have been dissected by all these methods. As with all clocks, the locomotor clock may control various overt rhythms, not merely the rhythm that was used to identify it (see Section 3.11.3.1).

All efforts to localize clocks must be preceded by a careful analysis of the characteristics of the overt rhythm being studied (e.g., locomotion) under a variety of lighting conditions. Such studies are sometimes referred to as revealing the "formal properties" of the rhythm. Essential information includes the free-running characteristics of the rhythm (in both continuous dark (DD) and continuous light (LL) and measurement of the free-running period lengths. This information is necessary in order to detect perturbations of these characteristics in later experiments. A uniform sequence of experimental steps has then been followed for many rhythms. The traditional first steps to clock localization involve ablation and transplantation of candidate structures. Elimination of photoreceptors (e.g., eyes, ocelli, brain) will lead to a free-running rhythm similar to that seen in DD. The removal of certain structures may lead to arrhythmicity (i.e., loss of rhythmicity in the phenomenon, not loss of the phenomenon). Arrhythmicity can be produced by removal of the clock itself, but will also be produced if the clock is disconnected from the outputs that it controls. For example, removal of the subesophageal ganglion (SEG) leads to arrhythmic locomotion not because the clock is located in the SEG, but because the optic lobe clock controls the locomotor centers in the thoracic ganglia by nerve pathways that run through the SEG. Consequently, several structures will be found whose removal causes arrhythmicity in a phenomenon. The clock is usually assigned tentatively to the site that is anatomically closest to the photoreceptors. This tissue is then examined *in vitro* for its ability to generate circadian rhythmicity of nervous activity, hormone release, etc. When an endocrine output is suspected, the structure is implanted into arrhythmic hosts and the restoration of rhythmicity is examined. The fact that such experiments often work, illustrates that circadian clocks and endocrine cells are frequently located close to each other in the same piece of tissue (see Section 3.11.3.2). Since this sequence of experimental steps relies on perturbations of an overt rhythm, it is clear that the clock identified has an output that communicates temporal information to other parts of the organism. These clocks are therefore true clocks in the sense that they not only keep time but they communicate timing to other cells. A nervous output is traditionally associated with the control of local, behavioral, rhythms and an endocrine output with more widespread effects in diverse cells and tissues. Consequently, clocks that control hormones are able to exert the most profound and widespread effects, making such clocks the most important ("master clocks") in the

organism. Thus, hormones represent a key controlled output of master clocks (see Section 3.11.3.2).

The elucidation of clock genes and molecular oscillators in *Drosophila* (see **Chapter 4.11**) has both revolutionized and complicated the methods for localization of clocks. Studies of the expression of the clock genes (mainly *per* and *tim*) and of their coded proteins have resulted in the description of numerous cellular loci that are potential cellular clocks. In situations where traditional techniques have shown that a circadian clock is contained in a particular tissue, the presence of cells within it that exhibit cycling of clock gene products provides compelling evidence that these are the cells within the tissue that are responsible for the generation of rhythmicity, i.e., the "clock cells" in the tissue. Indeed, the molecular oscillator (see **Chapter 4.11**) was unraveled in *Drosophila* primarily in the context of the cells in the optic lobe that express clock genes. In addition, molecular oscillators have been found in a number of sites, both within the central nervous system (CNS) and in other tissues, the functional significance of which has not been studied. Consequently, it is not yet known whether or not such cells do in fact convey information about time to other cells. Since communication of temporal information to other cells is an essential feature of true circadian clocks, it is often unclear whether these cells are functional clocks. The functions of these novel loci of clock cells and the mechanisms by which they are coordinated with one another represent important new areas of circadian biology.

It is important to note that the models of the molecular oscillator require that the clock genes are transcribed with circadian periodicity, resulting in circadian changes in the levels of clock gene mRNA and the resulting clock proteins (PER, TIM, etc.) in the cell. These proteins act (indirectly) as transcription regulators that move into the nucleus with circadian periodicity. Consequently, cells that express clock genes are candidate clock cells only if the mRNA and/or protein levels show circadian cycling. Specifically, it should be demonstrated that these levels free-run in DD, and that clock protein migration into the nucleus also occurs with a rhythmicity that free-runs in DD. These criteria must all be fulfilled by true clock cells. These clock cells are normally found in groups of ten or more cells, and the cells are coupled together by gap junctions and/or common synaptic or hormonal inputs (examples in sections below). These features suggest that a single clock cell may not have all the properties of a complete circadian clock. The only known case of a single cell that has all the properties of a clock is the chick pinealocyte, which is photosensitive and generates a rhythmic output of melatonin *in vitro* (Pickard and Tang, 1994).

In some cells that show daily cycling of clock gene expression and clock protein abundance, these rhythms cease in DD. The failure of rhythmicity to free-run in such cases is evidence that it is not generated endogenously within the cells that express the clock genes. Rhythmicity in such cells must be driven, usually by rhythmic inputs from hormones or nerves. Thus, hormones play an important role as inputs that drive rhythmicity in oscillators of this type (see Section 3.11.3.3). These cellular oscillators are not clock cells, because their rhythmicity is driven by other cells. In other words, true clocks are responsible for generating the driving inputs to these cellular oscillators. This arrangement leads to the notion that oscillators are organized into a hierarchy, with master clocks driving rhythmicity in other oscillators via hormones or nerves. Driven oscillators are found in the CNS as well as in peripheral tissues and true clocks are found in peripheral tissues as well as the CNS. Examples are found throughout the sections below. In the context of hormones, any feedback loop (see **Chapter 3.8**) can become an oscillator (i.e., become rhythmic) if it receives rhythmic driving input from a true clock. Removal of the clock input will cause such oscillations to cease. If oscillations continue after removal of the known clock inputs, the presence of unidentified clocks within the feedback loop is implied.

In yet other cells, the clock genes and their products may show no cycling, even in L : D. Such cells presumably have no molecular oscillators and therefore have no role in timekeeping. That clock genes may be expressed in cells with no role in timekeeping has raised the possibility that clock proteins may be multifunctional and have roles in cells other than as components of the molecular oscillator. This notion gains support from the fact that PER and TIM are normally found in cells in great abundance, at levels comparable to those of secretory proteins. Such high levels would be quite unnecessary for their roles as transcriptional regulators. Further, PER and TIM proteins may be found at great distances from the nucleus, such as along the length of axons (Sauman and Reppert, 1996a). Functions of clock genes in noncircadian phenomena include cocaine sensitization (Andretic *et al.*, 1999) and the ultradian male courtship rhythm of *Drosophila* (Hall, 2002, 2003).

3.11.3. Brain Clocks and the Endocrine System

There are two distinct areas in the insect brain that are well documented as centers of circadian timekeeping. One is located in the optic lobe and has been studied in depth; the second is located in the protocerebrum (**Figure 1**). Both of theses areas have been elucidated using the adult locomotor rhythm as the monitored output rhythm and are frequently referred to as locomotor clocks. This terminology does not imply that no other rhythmic phenomena are controlled by these areas, but rather that other outputs have received little experimental attention. Recent studies of the neuroarchitecture of these clocks, summarized below, reveal a complex association between the clock cells and cerebral neuropeptides and reveal pathways by which these clock areas, either separately or in cooperation with each other, control the rhythmic release of various hormones.

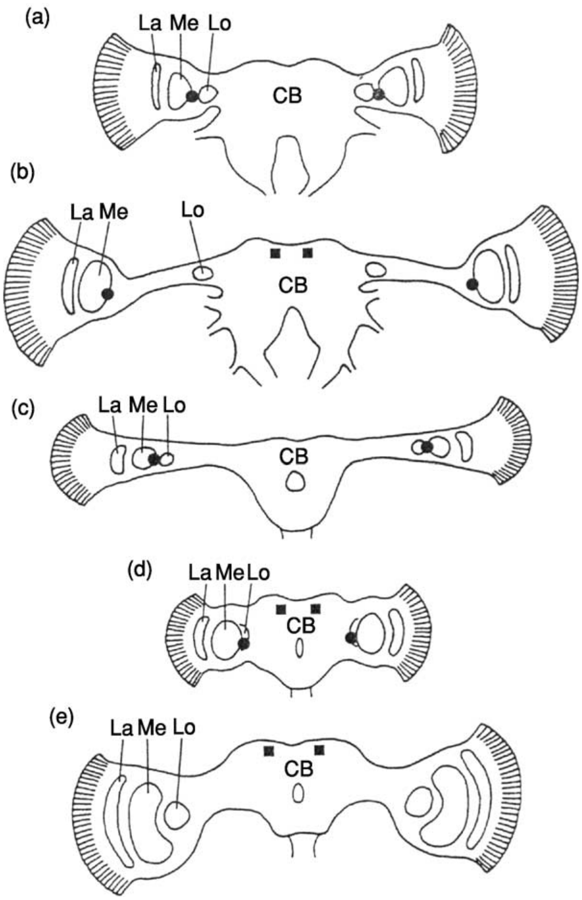

Figure 1 Diagrams of the brains of several insects, indicating the presence and location of the optic lobe clock (filled circles) and protocerebral clock (filled squares). (a) Cockroach; (b) cricket; (c) beetle; (d) fly; and (e) moth. The optic lobe neuropiles are lamina (La), medulla (Me), and lobula (Lo). Optic lobe clock neurons near the accessory medulla project to the protocerebrum in the central brain (CB) and distally to the medulla (see text). (Reproduced from Helfrich-Förster, C., Stengl, M., Homberg, U., **1998**. Organization of the circadian system in insects. *Chronobiol. Internat. 15*, 567–597.)

The structure, physiology, and molecular biology of these clocks has been reviewed extensively (Helfrich-Förster *et al*., 1998; Hall, 2003) but always in the context of behavioral rhythms. The treatment below differs significantly from previous reviews because it is focused on the relevance of this information to endocrinologists and the control of endocrine rhythms. Two central conclusions emerge. First, these clocks function to control rhythmicity in both behavioral and endocrine rhythms and constitute a key component of the circadian system in insects, with similarities to the suprachiasmatic nucleus in mammals. Second, hormones perform at least two functions in the circadian system; they are key controlled outputs of clocks which convey temporal signals to distant tissues through the hemolymph, but they also participate in the regulation of clocks (e.g., control of phase of the output) and consequently are components of the circadian timekeeping system itself.

3.11.3.1. Optic Lobe Clock and Hormones

The optic lobe has been the subject of a comprehensive series of experiments employing the classical techniques of ablation, transplantation, and lesions in several species of cockroach (reviews: Page, 1985, 1988). The optic lobe of *Leucophaea maderae* isolated *in vitro* generates a circadian rhythm of compound action potentials that free-runs in DD (Colwell and Page, 1990). When the optic lobe is transplanted into a cockroach previously rendered behaviorally arrhythmic by bilateral lobectomy, locomotion gradually becomes rhythmic as the transplanted optic lobe develops neural connections with the host brain (Page, 1983). The location of this circadian locomotor clock within the optic lobe started to become apparent when an antiserum to crustacean pigment dispersing hormone (PDH) was employed in immunohistochemical investigations of the brain (Homberg *et al*., 1991a, 1991b; Nässel *et al*., 1991). The PDH-immunoreactive perikarya were located between the neuropiles of the medulla and the lobula, adjacent to the accessory medulla (a proximal appendix of the medulla). Immunoreactivity was present throughout the axons, enabling the projections to be traced. The cells possess one projection to the protocerebrum, a second that ramifies in the medulla, and commissures connecting to the contralateral cells (**Figure 2**). On anatomical

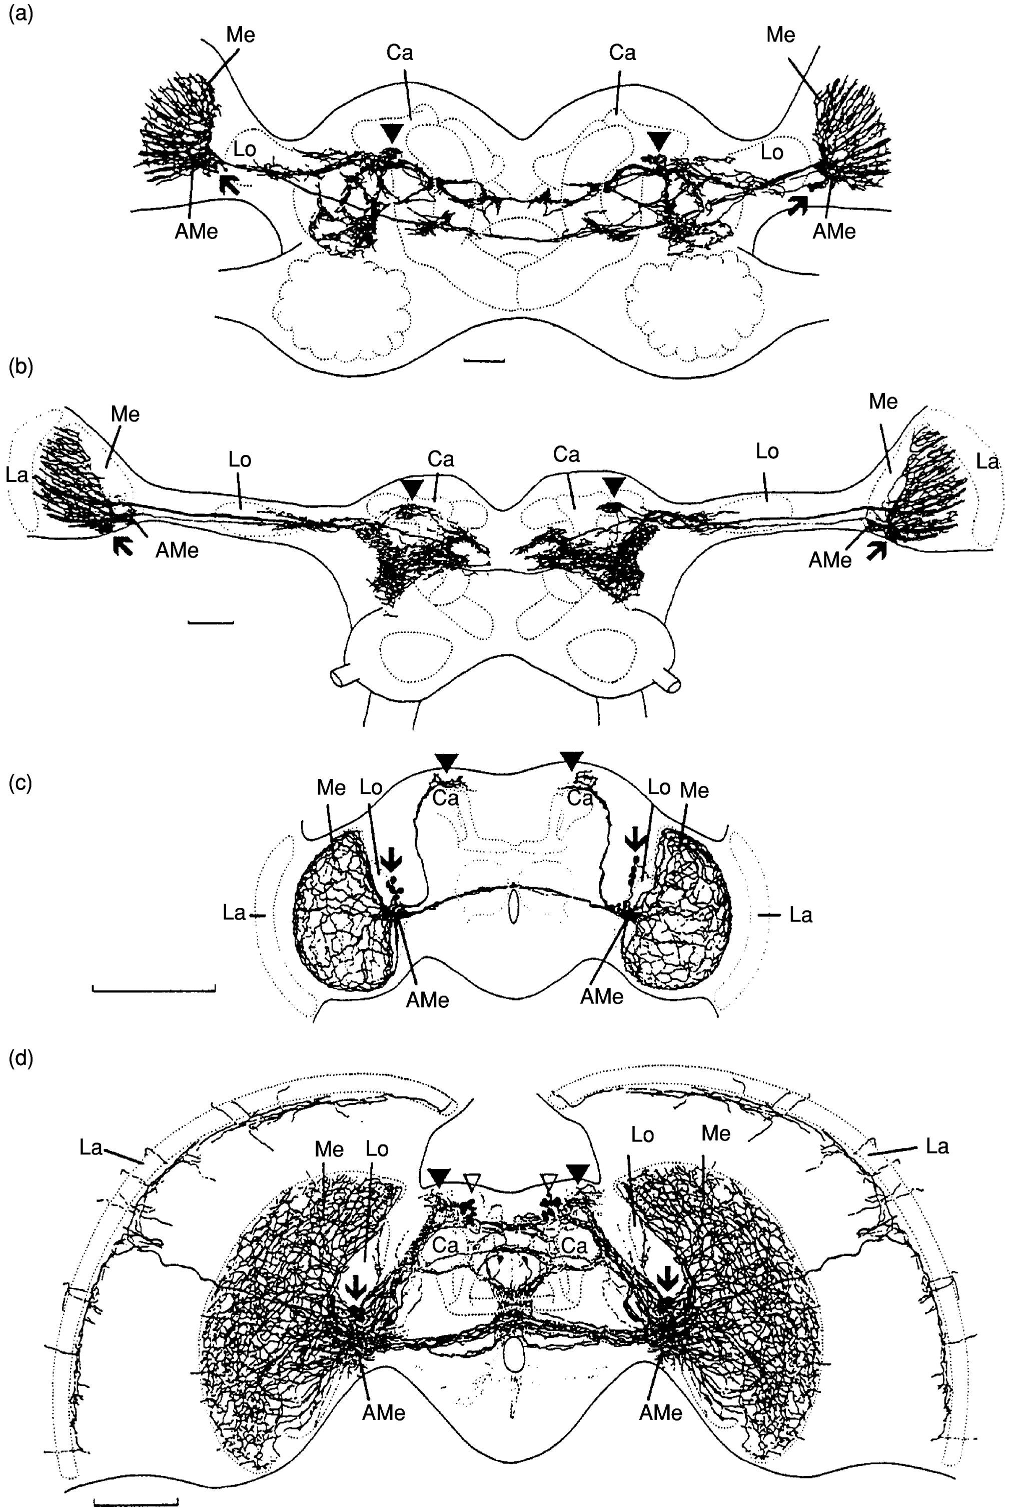

Figure 2 Axonal pathways of the presumed clock neurons of the optic lobe as revealed by pigment dispersing factor (PDF) immunoreactivity. (a) The cockroach *Leucophaea maderae*; (b) the cricket *Teleogryllus commodus*; (c) *Drosophila melanogaster*, (d) the blowfly *Phormia terraenovae*. Arrows point to the perikarya located adjacent to the accessory medulla (AMe). In all species, extensive ramifications of axons occur in the medulla (Me) and central projections occur to an area of the protocerebrum (filled arrowheads) just anterior to the calyces (Ca) of the corpora pedunculata (outlined with dots). Commisures connecting contralateral sets of neurons are also visible. In *P. terraenovae* (d), additional PDF-reactive neurons are found in the protocerebrum (open arrowheads), which project to the corpus cardiacum (not visible in the figure). Scale bar = 200 μm. (Reproduced from Helfrich-Förster, C., Stengl, M., Homberg, U., **1998**. Organization of the circadian system in insects. *Chronobiol. Internat. 15*, 567–597.)

grounds, these neurons are well suited to receive photic input from the eye and to relay it to the central brain (Stengl and Homberg, 1994). The position of these cells corresponded closely to the region of the optic lobe to which the clock had been previously assigned using microlesions (Sokolove, 1975). Following knife cuts between the lobula and protocerebrum, cockroaches regained behavioral rhythmicity in synchrony with regeneration of the PDH-reactive fibers (Stengl and Homberg, 1994). Ablation and transplantation of the accessory medulla confirmed that this small region of the optic lobe contained a clock (Reischig and Stengl, 1997). A similar pattern of branching of PDH-reactive neurons is seen in diverse insect species (Sehadová *et al.*, 2003; **Figure 2**). Orthologs of PDH are found in insects and are termed pigment dispersing factors (PDFs) (Rao and Riehm, 1993). An intimate association between neuropeptide(s) and circadian clocks was thus established.

Concomitant studies of *per* expression in *Drosophila* had identified two major sites of *per* cycling in the adult brain (Ewer *et al.*, 1992; Frisch *et al.*, 1994). These sites were dubbed the "lateral neurons," located at the junction of protocerebrum and optic lobes, and the "dorsal neurons," located above the corpora pedunculata in the protocerebrum. These are the only sites of cycling *per* expression in the brain that are present from the first instar onwards (Kaneko *et al.*, 1997). Critically, the PDF-reactive neurons expressed *per* (Helfrisch-Förster, 1995, 1997), showing that these neuropeptide-containing cells were indeed clock cells. But PDF-reactivity was not seen in *all* of the lateral neurons (only in a "subset") and was absent from all other cells that expressed *per*, including the dorsal neurons. Therefore, no universal role of PDF in clock cells can be expected. Together, these studies show that the optic lobe clock consists of a small group of neurons in which *per* expression cycles. Most, but not all, of these cells coexpress PDF, which enables the axons to be traced both distally towards the eyes and centrally into the protocerebrum. These cells are commonly associated with the accessory medulla.

The accessory medulla contains a variety of neuropeptides other than PDF, including allatostatins, FMRFamide, gastrin/cholecystokin, leucokinin I, and corazonin (Petri *et al.*, 1995). Local injection close to the accessory medulla of PDF, allatotropin, serotonin and γ-aminobutyric acid (GABA) all induce phase shifts (Petri and Stengl, 1997; Petri *et al.*, 2002; Saifullah and Tomioka, 2002, 2003) (see **Figure 20**). These recent findings imply that the optic lobe clock is subject to a sophisticated array of neurochemical manipulations. These seem to act primarily to adjust the phase of the rhythm generated by the clock cells and may either reinforce or contradict the photic information received from the environment. The complexity of organization of the optic lobe clock invites the expectation that it is not solely involved with the locomotor rhythm.

Several points of contact between the PDF-expressing lateral neurons and the neuroendocrine system in the head of adult *Drosophila* were revealed by Siegmund and Korge (2001) using a GAL4 enhancer trap system. The clock cells (sPDFMe cells in **Figure 3**) form synaptic connections in the protocerebrum with two large neurosecretory cells that terminate on the corpus allatum (CA) cells of the ring gland (**Figure 3**). At least one of these cells was thought to contain a *Manduca*-allatostatin-like peptide. These connections provide a structural pathway for circadian control of the CA (see Section 3.11.5.1). The clock cells follow the axons of two other neurosecretory cells for about 70 μm and seemed to directly contact their collaterals. These cells were very similar in size, position, and morphology to the prothoracicotropic hormone (PTTH) cells of *Bombyx mori* (Mizoguchi *et al.*, 1990) and *Manduca sexta* (Westbrook and Bollenbacher, 1990) and were presumed to contain the PTTH of *Drosophila* (see **Chapter 3.2**). Thus, a structural pathway for circadian regulation of PTTH was postulated. A close association between clock cells and PTTH cells has been described in many species (see Section 3.11.4.1.2) but this association is more commonly with clock cells in the protocerebrum than in the optic lobe. An interesting feature of these cells in *Drosophila* was that the neurosecretory axons formed terminal arborizations within the prothoracic gland (PG) region of the ring gland. This arrangement suggested that *Drosophila* PTTH was delivered directly to the PG cells and might not enter the hemolymph as a classical hormone.

3.11.3.2. Protocerebral Clock and Hormones

The picture that is emerging from recent studies is that the optic lobe and protocerebral clocks are not the distinct entities assumed in the earlier literature. The presence of a circadian clock in the protocerebrum of various insects has been inferred from traditional lesion experiments and is only now receiving analysis at the level of neuroarchitecture and molecular biology. Some species appear to have both optic lobe and protocerebral clocks, while other species seem to have one but not the other (see **Figure 1**). But the absence of evidence is not evidence of absence; for example, *per/tim* expressing

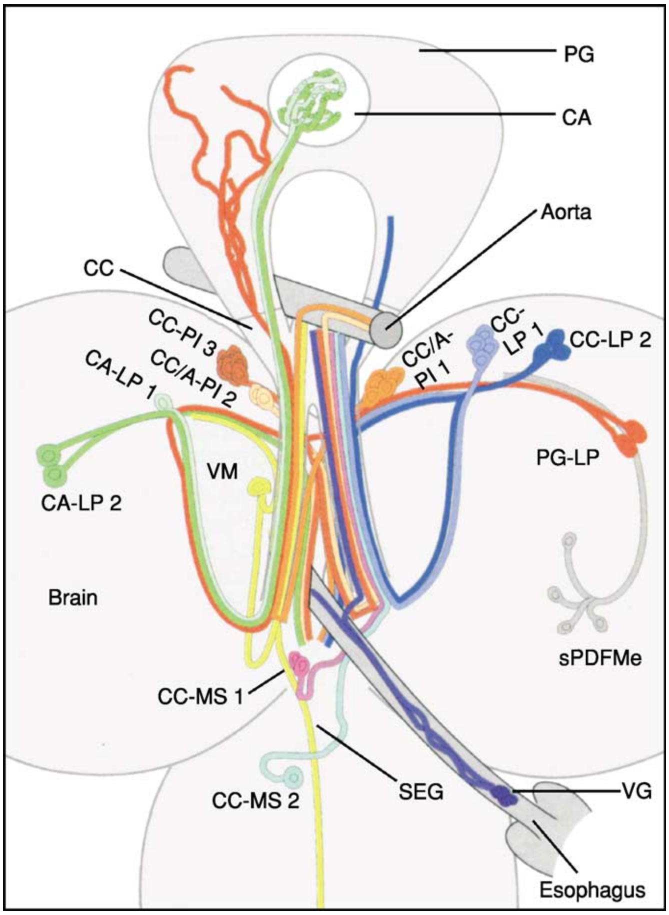

Figure 3 Axon pathways in the brain of *Drosophila melanogaster* that connect the lateral neurons of the optic lobe (sPDFMe) with the cerebral neuroendocrine system. In this diagram, the subesophageal ganglion is depicted in the lower part (SEG) and the ring gland in the upper part. CA is the corpus allatum, CC the corpus cardiacum, and PG the prothoracic gland. Arborizations of the sPDFMe neurons overlap with those of the two PG-LP neurons that directly innervate the PG and probably represent the PTTH neurons (see text). The CA is innervated by three neurons arranged in two groups (CA-LP1 and CA-LP2) and thought to contain allatostatin-like peptide, one of which passes in close proximity to the terminals of the sPDFMe neurons. The CC is innervated from the CC-LP1 and CC/A-PI 1, 2, and 3 neurons, which may receive input from the dorsal group of clock neurons (not shown here; see **Figure 4**). VM neurons are immunoreactive for eclosion hormone. (Siegmund T., Korge G., **2001**. Innervation of the ring gland of *Drosophila*. *J. Comp. Neurol.* *431*, 481–491; © Wiley. Reprinted by permission of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.)

neurons close to the accessory medulla of *Manduca* (not shown in **Figure 1e**) have been recently described (Wise *et al.*, 2002). In crickets and flies (**Figure 1b** and **d**) the failure of optic lobe lesions to completely abolish the locomotor rhythm has been ascribed to the presence of a protocerebral clock. In saturniid moths, the optic lobes were entirely unnecessary for rhythmic locomotion (Truman, 1974), which was found to be regulated by a protocerebral clock entrained by extraocular photoreception. Similarly, the eclosion of silkmoths (see Section 3.11.4.3) was also found to be controlled in this way (Truman and Riddiford, 1970; Truman, 1972b). The release of PTTH that terminates pupal diapause is regulated by a photoperiodic clock in the protocerebrum (Bowen *et al.*, 1984). A close association between the PTTH cells and "clock cells" in the protocerebrum has been described by Sauman and Reppert (1996b) in *Antheraea pernyi* and by Terry and Steel (2004) in *Rhodnius prolixus* (see Section 3.11.4.1.2).

Studies of *per* expression in the brain of adult *Drosophila* revealed two groups (of two and 15 cells) of dorsal neurons in the protocerebrum (Ewer *et al.*, 1992). These cells do not express PDF and consequently their connections could not be traced by immunohistochemical methods and the cells were not accessible to targeted molecular lesioning in order to study their functions. Consequently, much less is known of these cells than the lateral neurons. Important information regarding the neuroarchitecture of clock cells in the *Drosophila* brain

was obtained using a GAL4 expression system (Kaneko and Hall, 2000). A third group of dorsal neurons (about 40 cells) was revealed (**Figure 4**), together with interconnections between the various dorsal and lateral neurons. The lateral neurons of the optic lobe clock (see above) were found to project to terminals in the dorsal protocerebrum, as previously found using PDF-immunoreactivity for tracing. These endings appeared to be connections with the dorsal neurons, some of which sent reciprocal processes back to the lateral neurons. Therefore, the protocerebral and optic lobe clocks are not distinct entities, but rather components of an integrated mosaic of clock cells in the brain.

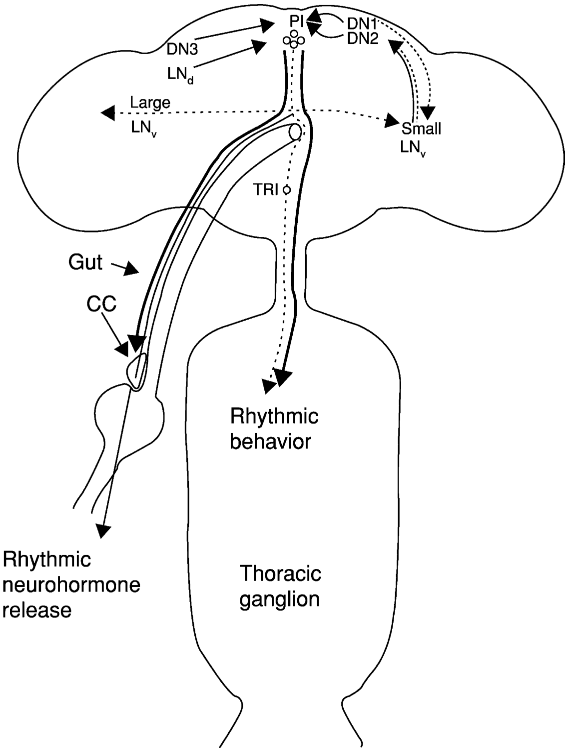

Figure 4 Deduced patterns of interactions between clock neurons and neurosecretory cells in adult *Drosophila melanogaster* and their probable connections with neuroendocrine cells of the pars intercerebralis. These connections may drive the rhythms in neurohormone release reported for other insects (see text). The LN_v (small and large) comprise the putative optic lobe clock of **Figure 1**. The large cells give rise to the arborizations in the medulla and the commissures between the hemispheres (see **Figure 2**). The small cells connect with the dorsal neurons (DN1, DN2) and receive reciprocal innervation from the DN1. All three groups of dorsal neurons (DN1, DN2, DN3) innervate the pars intercerebralis where we suggest they drive rhythmic activity in the neurosecretory cells and therefore, rhythmic neurohormone release from the corpus cardiacum (CC). The dorsal lateral neurons (LN_d) may also contribute to this input. Thus, clock cells throughout the brain converge on neurosecretory cells. Rhythmic locomotor behavior is also driven through (unspecified) neurons in the protocerebrum that project to the thoracic ganglion. (Modified with permission from a diagram of the clock neurons that control behavior in *Drosophila* by Kaneko, M., Hall, J.C., **2000**. Neuroanatomy of cells expressing clock genes in *Drosophila*: transgenic manipulation of the *period* and *timeless* genes to mark the perikarya of circadian pacemaker neurons and their projections. *J. Comp. Neurol. 422*, 66–94.)

All three groups of dorsal neurons appeared to terminate close to the neurosecretory cells in the pars intercerebralis. Kaneko and Hall (2000) did not consider the relevance of their data to the neuroendocrine system. We interpret their evidence as indicating that the medial neurosecretory cells receive direct circadian input from the "dorsal neurons." The dorsal neurons are neurally coupled with the lateral neurons of the optic lobe. Therefore, the lateral neurons provide an indirect input to the neurosecretory cells, via the dorsal neurons (**Figure 4**). In some of the dorsal neurons, *per* expression cycles in antiphase to other dorsal neurons (and to the lateral neurons) (Kaneko *et al*., 1997), raising the intriguing prospect that the rhythms (in hormones?) driven by this system of clock cells may not all have the same phase. The data of Siegmund and Korge (2001) (see Section 3.11.3.1) indicate that some of the lateral neurons may bypass the dorsal neurons and make direct synaptic contact with neurosecretory cells. Thus, the neurosecretory cells appear to receive circadian input from all the major groups of "clock cells" in the brain. Therefore, we infer that most, if not all, of the neurosecretory cells would express rhythmicity.

In conclusion, the anatomically separate groups of clock cells in the brain appear to be interconnected. The nature of these interconnections may vary between species and thereby account for apparent species variations in the location and properties of the clock controlling a particular rhythm. The network of clock cells regulates rhythmicity in both behaviors and the endocrine system. As such, it is able to influence, if not drive, rhythmicity throughout the organism. It probably represents a master clock that is analogous to the suprachiasmatic nucleus (SCN) of mammals. The SCN is known to be influenced by an array of inputs, including inputs from other oscillators such as the ocular retinae, pineal gland, and parietal eye. The sections below illustrate that there is accumulating evidence that oscillators outside the brain provide input to the timing system in the brain of insects, which raises the prospect that the insect circadian system will also be comprised of multiple coupled oscillators in several anatomical locations, which communicate with each other primarily by hormones.

3.11.3.3. Peripheral Oscillators and Hormones

A variety of cells and tissues has been identified that display circadian cycling of a physiological process and/or clock gene expression. Some of these loci are able to generate rhythmicity *in vitro*, free-run in aperiodic conditions, and transmit a rhythmic output to other cells; such cells are therefore true clocks. Three such peripheral clocks have been described. The most fully characterized of these is the PG clock of *Rhodnius* (see Section 3.11.4.1.3) that generates rhythmic synthesis of ecdysteroids; PGs can be entrained by light *in vitro*, exhibit circadian cycling of PER, and communicate rhythmicity to ecdysteroid-sensitive cells via the rhythm of ecdysteroids in the hemolymph. In *Drosophila*, chemosensory hairs of the antennae exhibit cyclic expression of *per* (Krishnan *et al.*, 1999) (**Figure 5**) and this cycling is necessary for the circadian rhythm of olfactory responsiveness. In several moths, rhythmic movement of sperm along the duct system is regulated by a circadian clock, but its location is unclear (see Section 3.11.5.2.2); *per* expression occurs in part of the duct epithelium but this may not be the site of the clock that controls sperm movement.

A number of other loci have been described for which the criteria of a true clock have either not been met or have not been examined. These loci are called peripheral oscillators, not clocks. In *Drosophila*, Plautz *et al.* (1997) used a luciferase reporter driven from the promoter of *per* to identify oscillatory structures. Numerous epidermal structures exhibited a rhythmic glow. Some of these rhythms free-ran in DD and could be reset by light in pieces of the insect (e.g., a leg). The significance of these oscillators remains obscure since no output from them is known. Hege *et al.* (1997) obtained similar data for Malpighian tubules. Giebultowicz *et al.* (2000) found that tubules that were transplanted into another insect appeared to lose light sensitivity and were unable to respond to humoral signals from the host. The data are consistent with a requirement for entrainment via intact connections between the tubules and the rest of the animal. It is not known whether the tubule rhythm has a functional significance nor whether rhythmicity can be transmitted to other cell types.

In order to determine whether such peripheral oscillators possess clock properties, it will be necessary to employ *in vitro* techniques and eventually to study cell lines for timekeeping properties. These approaches are extensively used in mammalian studies. For example, SCN cell lines produce a wide array of signaling molecules (Hurst *et al.*, 2002) and can communicate rhythmicity to other cells (Allen *et al.*, 2001), confirming the central importance of the SCN cells in circadian timekeeping. Fibroblasts (Yagita *et al.*, 2001) and smooth muscle cells (Nonaka *et al.*, 2001) are able to express the same clock genes as SCN cells and do so with circadian periodicity, but expression of these genes is both induced (Nonaka *et al.*, 2001) and phase-set (McNamara *et al.*, 2001) by hormones. The induced rhythmicity in these cells is not transmitted to other cells. In mammals, peripheral oscillators exhibit circadian expression of clock genes, but this rhythmicity is driven by external factors and is not transmitted to other cells. Such oscillators are not clocks (Allen *et al.*, 2001). The

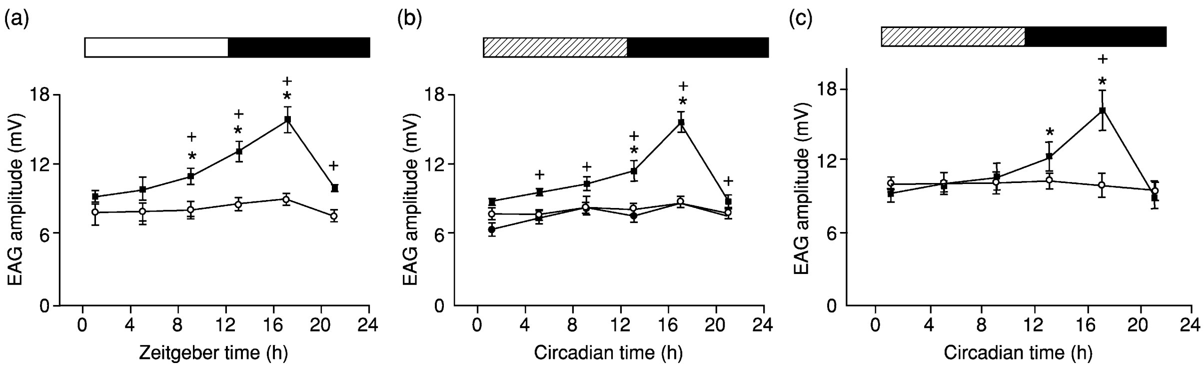

Figure 5 The circadian rhythm of olfactory responsiveness in *Drosophila melanogaster* as seen in electroantennogram records (EAG). Dark portions of horizontal bars indicate scotophase in (a) and subjective scotophase during continuous darkness in (b) and (c); light portions of the bar are photophase in (a), whereas subjective photophase in (b) and (c) is shown as a gray bar. Filled squares in (a), (b), and (c) are wild-type flies that show a rhythm in EAG amplitude that free-runs in DD ((b) and (c)). Flies with null mutations of clock genes (*per*^{0}, open circles; *tim*^{0}, filled circles) show no rhythmicity. Open squares in panel (c) depict a transgenic *per* strain (7.2.2) in which the peripheral *per* oscillator fails to function. Circadian rhythms in olfactory responses of *Drosophila melanogaster*. *Nature 400*, 375–378); © Macmillan Publishers Ltd.)

most common entraining signals to such oscillators are hormones (Herzog and Tosini, 2001; McNamara *et al*., 2001; Balsalobre, 2002). In insects, the roles of hormones as entraining agents to peripheral oscillators have not yet been studied. This will be a fruitful new area for insect endocrinologists.

In conclusion, insects posses numerous peripheral oscillators, but their properties and significance in all but a few cases have yet to be studied. Related research with mammals creates the expectation that hormones will emerge as the major entraining signals to such oscillators. In insects, a number of peripheral oscillators are photosensitive (Giebultowicz, 2000), but this does not reduce the potential importance of hormones as time signals. A striking example is provided by the PG clock of *Rhodnius*, which is entrainable both by light and by PTTH (see Section 3.11.4.1.3). Indeed, it has been argued that the known diversity of rhythms in any organism requires complex communication pathways between central timing systems in the brain and tissue-specific peripheral oscillators (Ikonomov *et al*., 1998; Gillette and Mitchell, 2002; Kalsbeek and Buijs, 2002). Such communication is most readily achieved by hormones.

3.11.4. Developmental Processes and Hormones

3.11.4.1. Circadian Regulation of Developmental Hormones

There is evidence that all of the hormones involved in the regulation of development are under circadian control. The literature relating to PTTH, ecdysteroids, the juvenile hormones (JHs), and melatonin is presented below. The circadian regulation of the hormones that control ecdysis behavior is also reviewed as this is a behavior that is under circadian control which is also closely integrated with development. We suspect that it will be found that all of these hormones are integrated together under the control of a circadian system that governs the temporal organization of developmental events. This notion is implied by the pervasive nature of circadian control mechanisms at all levels of development and is supported by various lines of evidence presented below. The literature has yet to integrate these lines of evidence into a comprehensive regulatory scheme.

3.11.4.1.1. Gated head critical periods One of the oldest observations in the entire field of insect endocrinology was that decapitation resulted in an arrest of the molting process if performed early in the molt, whereas decapitation later had no effect (Kopec, 1922). The period of time over which this independence of molting from the head was achieved in a population of insects became known as the head critical period (HCP). The acquisition of head independence was believed to be quite abrupt in individuals, i.e., the HCP did not occur in individual insects, only in populations. To this day, the events that give rise to the HCP are not understood. Initially, it was surmised that release of PTTH gradually activated the PGs and then its release ceased at the HCP once activation was completed (Wigglesworth, 1934). This view prevailed for decades, despite contradictory findings. For example, it was found in *Rhodnius* that brains of insects prior to the HCP (presumably releasing PTTH) were unable to promote molting when implanted into headless hosts (Wigglesworth, 1934). It was later found (Wigglesworth, 1940) that this brain implantation experiment would only promote molting if the brains were taken from animals that had *passed* the HCP. This experiment clearly showed that PTTH release did not cease at the HCP (as later studies confirmed) (see Section 3.11.4.1.2), but failed to revise the understanding of the significance of the HCP.

Much later, neck ligation experiments showed that the HCP in a population of *Manduca* larvae was gated (Truman, 1972a). This finding was the first experimental evidence that a developmental event in insects was subject to circadian timing. In these experiments, the HCP was assumed to represent the length of time during which release of PTTH occurred (in a population?). In 1972, there was no reliable assay for PTTH with which to test this assumption. It was concluded that the time of PTTH release was controlled by a circadian clock. Several other visible events (prodroma) that occur during the molt to the pupal stage were also found to be gated, including evacuation of the gut when feeding ceases ("gut purge") and the onset of "wandering" behavior (Truman and Riddiford, 1974). Together, these findings demonstrate that a number of events during molting in *Manduca* are subject to circadian timing and laid a foundation for later studies of the circadian organization of development (see sections below). However, numerous subsequent studies, outlined below, clearly refute the notion that the HCP corresponds to the time of PTTH release.

During the 1980s, doubts were raised about the adequacy of neck ligation experiments for indentifying times of release of PTTH (see **Chapter 3.2**). Using *Samia cynthia*, Fujishita and Ishizaki (1981) found that the HCP for larval molting could be

phase-shifted and that gating of the HCP persisted in DD and was lost in LL. The HCP for gut purge at the pupal molt was also responsive to phase shifts (Fujishita and Ishizaki, 1982). These findings demonstrated clearly that the gating reported earlier in *Manduca* was indeed subject to formal circadian control. However, Fujishita and Ishizaki (1982) were not convinced that the HCP represented the time of PTTH release and observed that release could begin before the HCP and/or continue after it. Sakurai (1984) made similar observations using *Bombyx* and noted that if release of PTTH took place outside the HCP, traditional neck ligation experiments would be unable to detect it. Overall, these studies showed that the HCP was a manifestation of a circadian control mechanism governing many aspects of development, but its underlying nature remained elusive. Clearly, techniques that quantified the hormones involved were required.

A bioassay for PTTH was employed by Bollenbacher *et al.* (1987), who reported PTTH in the hemolymph of fourth instar *Manduca* during the scotophase of the HCP for gate one larvae. The absence of PTTH from the hemolymph during both the preceding and the subsequent photophases supported the notion of gated PTTH release during the HCP. But no data were obtained for the adjacent scotophases, so it was not known if this release was repeated. The release of PTTH from brains of *Bombyx* was examined every 12 h for all 12 days of the fifth instar by Shirai *et al.* (1993). PTTH release was reported on all but three of the 24 time points studied, clearly showing that PTTH release was not confined to the HCP. Their published data show that PTTH release from the brain was higher during the scotophase than during the following photophase, suggesting that PTTH release occurs with a daily rhythm. However, Shirai *et al.* (1993) preferred to interpret their data as five separate periods of PTTH release over 12 days, not as a rhythm. In *Rhodnius*, PTTH is released throughout larval–adult development with a clear daily rhythm (Vafopoulou and Steel, 1996a). The work with *Rhodnius* is discussed in greater detail in the sections below. In the context of the HCP, it should be noted that the amplitude of the rhythm increased greatly *after* the HCP, showing that most of the PTTH released during development was unrelated to the HCP. This finding incidentally explains the originally paradoxical finding of Wigglesworth (1940) that brains of animals that had passed the HCP were more effective at inducing the molting of decapitated hosts than were brains of animals before the HCP. *Rhodnius* is one of the many insects in which the HCP is not gated (Knobloch and Steel, 1987). A fluoroimmunoassay (FIA) for PTTH was employed by Dai *et al.* (1995) to examine PTTH release from brains of both fourth and fifth instar larvae of *Bombyx*. PTTH release was found on every day of both instars and again differences are visible in the data between photophase and scotophase. FIA revealed PTTH in the hemolymph on all these days and also throughout the pupal stage (Mizoguchi *et al.*, 2001, 2002). PTTH release for at least three consecutive days after the HCP was found in *Periplaneta americana* (Richter, 2001).

All these reports demonstrate clearly that release of PTTH is not confined to the HCP. Rather, PTTH is released throughout large portions, if not all, of an instar. Therefore, the notion that the HCP represents the time of PTTH release is not correct. This conclusion has been reached by Vafopoulou and Steel (1996a), Sakurai *et al.* (1998), and Mizoguchi *et al.* (2002), with each set of authors employing different pathways of reasoning. Sakurai *et al.* (1998) suggested that the HCP represents a time during which the PGs become more responsive to PTTH and the targets of ecdysteroids become more responsive. Mizoguchi *et al.* (2002) suggested that the HCP might be mediated by the innervation of the PGs found in moths. None of these possibilities requires any change in PTTH release at the HCP. It should be recalled that the HCP represents the time when PGs become able to maintain steroidogenesis without input from the head. As such, the HCP signals a change in the behavior of the PGs, rather than of the head. Despite the continuing enigmatic nature of the HCP, it must be emphasized that its definition and its gated nature (in certain species) have not been questioned. The HCP remains the original well-documented event in insect development that is under circadian control.

3.11.4.1.2. Prothoracicotropic hormone The timing and pattern of release of PTTH during development has been studied extensively in the blood-feeding bug *Rhodnius*. *Rhodnius* represents a particularly favorable experimental animal for the study of circadian phenomena in the endocrine system because of the remarkable precision it exhibits in the timing of developmental events following feeding. Many animals can be fed a large blood meal simultaneously and thus the growth and development of a whole population is synchronized with remarkable precision. This synchrony is maintained throughout development, probably because the insects do not feed after the initiation of development and will not feed until after ecdysis to the next instar. Feeding is known to affect developmental rates in other insects (Steel and Davey, 1985).

Further, the long length of the last larval instar (21 days) makes it possible to distinguish events that occur daily from those which occur on the longer timescale of development. The first clear evidence of a circadian rhythm in PTTH release was thus obtained in *Rhodnius*. *In vitro* incubation of *Rhodnius* brains and quantification of the amount of PTTH released by an *in vitro* bioassay (Vafopoulou *et al*., 1996) revealed that release of PTTH occurred as a daily rhythm throughout most of larval–adult development (Vafopoulou and Steel, 1996a). Indeed, PTTH immunoreactive peptide was released with a daily rhythm as shown on dot blots (Vafopoulou and Steel, 2002). PTTH release was not confined to a short period of time at the initiation of development. The rhythm of release consisted of prominent maxima during each scotophase and minima during each photophase (**Figure 6**). The rhythm free-ran in DD for at least five cycles with a period length close to 24 h and was temperature compensated (Vafopoulou and Steel, 1996b); it is therefore controlled by an endogenous circadian clock. The rhythm also free-ran in LL for three to four cycles, but with a period length somewhat shorter than that seen in DD. No rhythm was apparent after the fourth cycle in LL (Vafopoulou and Steel, 1996b). When animals were kept in LL for 30 days prior to sampling, rhythmicity in PTTH release was entirely lost (Vafopoulou and Steel, 2001); such "damping" of a circadian rhythm following chronic exposure to LL is a common phenomenon. Most interestingly, PTTH release in such animals was not just arrhythmic; it had ceased completely (**Figure 7**, left panels). When animals were transferred from LL to DD, the rhythmic release of PTTH was promptly reinitiated and continued to free-run in DD (**Figure 7**, right panels) (Vafopoulou and Steel, 2001). This clearly demonstrated that the circadian clock that regulates the rhythm of PTTH release is photosensitive. The rhythm of PTTH in the hemolymph of *Rhodnius* is synchronous with the daily rhythm of PTTH release from the brain (**Figure 8a**); the PTTH content of the brain also cycles during a day; it undergoes a sharp drop in the middle of each scotophase in synchrony with release of PTTH into the hemolymph (**Figure 8b**). About one-third of the PTTH content of the brain is released every scotophase; the level is

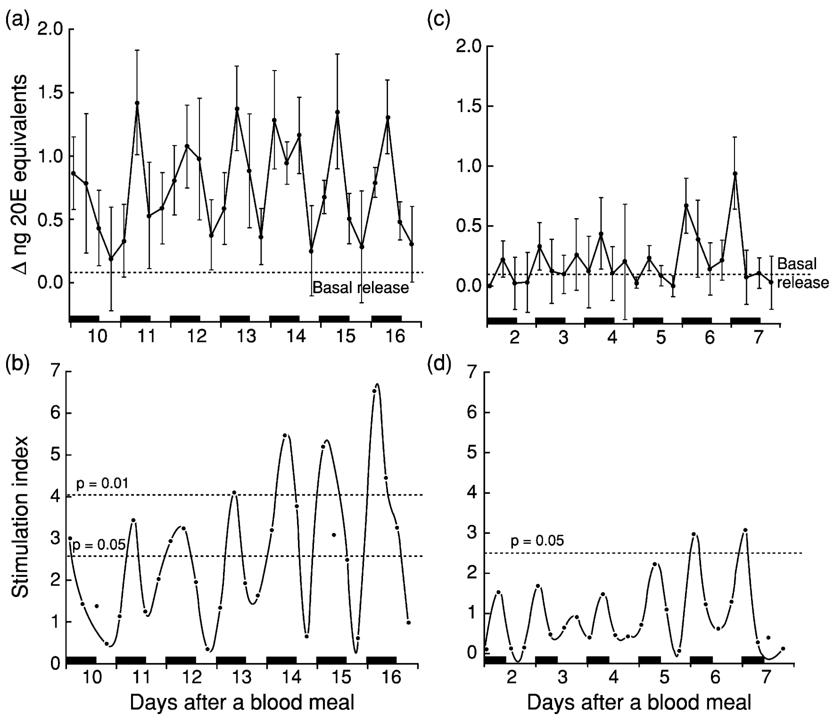

Figure 6 Circadian rhythm of prothoracicotropic hormone (PTTH) release from the brain–retrocerebral complex during larval–adult development of *Rhodnius prolixus*. Clear peaks of PTTH release occur every scotophase throughout days 10–16 of development (a), whereas deep troughs, close to background (basal release), occur every photophase. PTTH release is close to basal level in the beginning of the instar (days 2–5) (c). At the head critical period (HCP) on day 6, PTTH release increases sharply during the scotophase and marks the onset of rhythmicity. Panels (b) and (d) show the statistical significance of the levels of PTTH release shown in panels a and b, respectively. (Reproduced with permission from Vafopoulou, X., Steel, C.G.H., **1996a**. The insect neuropeptide prothoracicotropic hormone is released with a dialy rhythm: re-evaluation of its role in development. *Proc. Natl Acad. Sci. USA 93*, 3368–3372; © National Academy of Sciences, USA.)

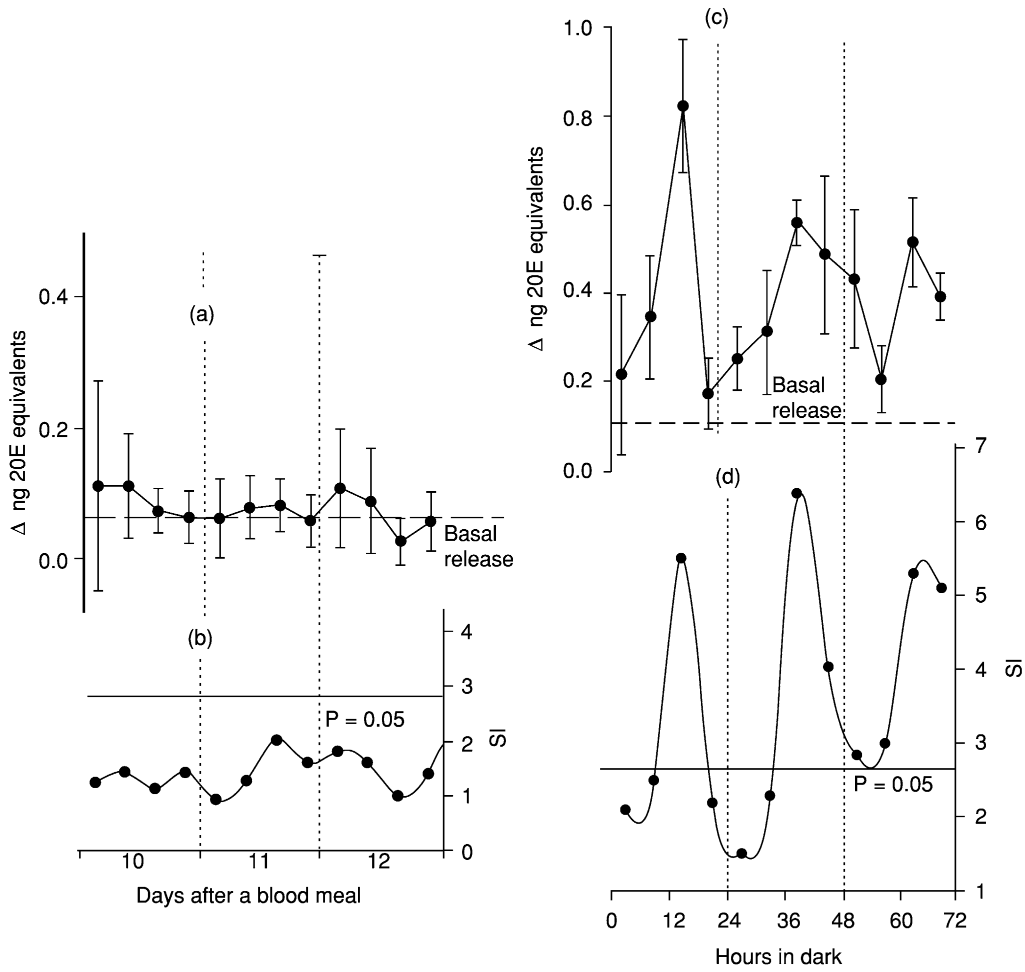

Figure 7 Induction of a daily rhythm of PTTH release from brain–retrocerebral complexes of *Rhodnius prolixus* by transfer from continuous light (LL) to continuous dark (DD). Larvae are arrhythmic following chronic exposure to LL, and there is near absence of PTTH release (a, b). Transfer to DD initiates a clear rhythm in PTTH release (c) with statistically significant peaks of roughly 24 h intervals in DD (d). (Reprinted with permission from Vafopoulou, X., Steel, C.G.H., **2001**. Induction of rhythmicity in prothoracicotropic hormone and ecdysteroids in *Rhodnius prolixus*: roles of photic and neuroendocrine Zeitgebers. *J. Insect Physiol. 47*, 935–941; © Elsevier.)

restored during the photophase each day, presumably by synthesis of the hormone. Thus, in *Rhodnius*, synthesis, release, and hemolymph levels of PTTH are all rhythmic events and are coupled to one another.

Synthesis of PTTH in *Rhodnius* occurs in a pair of large neurosecretory cells in the lateral region on each side of the protocerebrum (Vafopoulou *et al.*, 2004b). These PTTH cells lie adjacent to a small group of neurons immunopositive for the clock proteins PER and TIM (**Figure 16**) (Terry and Steel, 2004). These neurons are true clock cells since both PER and TIM exhibit circadian cycling in abundance and in migration in and out of the nucleus. The location of these clock cells in the brain is equivalent to the lateral group of clock neurons in *Drosophila*. PTTH has also been localized to the lateral neurosecretory cell cluster in other species as in *Bombyx* (Mizoguchi *et al.*, 1990), *Manduca* (Agui *et al.*, 1979; O'Brien *et al.*, 1988), and *Samia* (Yagi *et al.*, 1995) but not in all species examined (Závodská *et al.*, 2003). A similar proximity between PER-containing neurons and PTTH cells is seen in the moth *A. pernyi*, where this arrangement is believed to regulate the release of PTTH that terminates diapause in response to long days (Sauman and Reppert, 1996b). This information raises the interesting possibility that a similar, if not the same, neuronal clock mechanism may be involved in both circadian and photoperiodic regulation of PTTH release (see **Chapter 3.12**). In another moth, *Bombyx*, the PTTH levels in the hemolymph show a daily rhythmicity during larval (**Figure 9**) (Dedos and Fugo, 1999; Mizoguchi

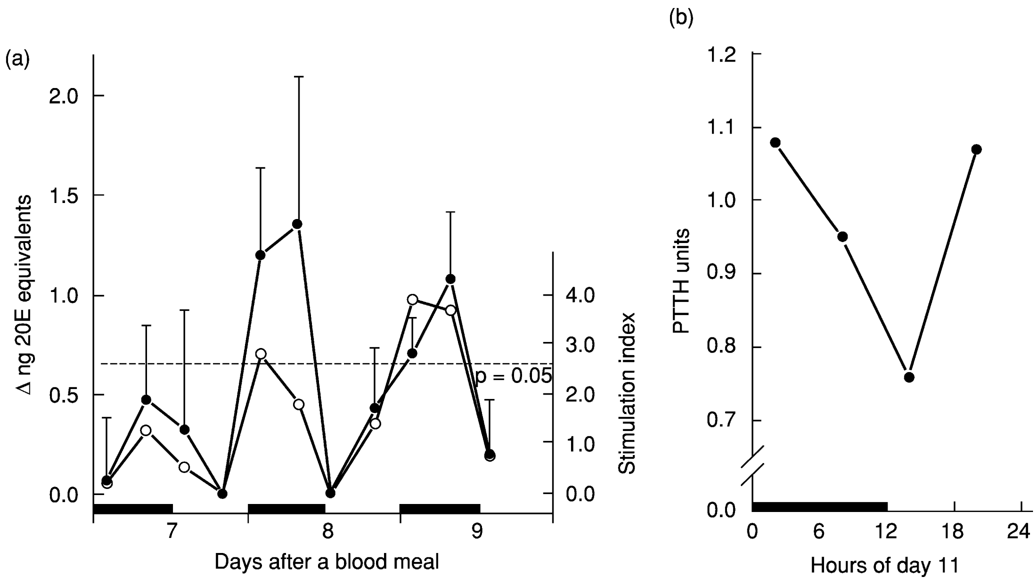

Figure 8 The daily PTTH rhythm in the hemolymph of fifth (last) larval instar of *Rhodnius prolixus* showing peaks during each scotophase (a). The pattern of the hemolymph rhythm parallels that of the PTTH release from the brain (compare with **Figure 6a**). Amounts of PTTH release (filled circles) are shown on the left axis and statistical significance (open circles) on right axis. Panel (b) shows rhythmicity in PTTH content of the *Rhodnius* brain; the brain PTTH content drops during the scotophase when the PTTH titer in the hemolymph is rising (compare a with b), suggesting release at night, whereas the brain content is replenished during the photophase, presumably by PTTH synthesis. (Reproduced with permission from Vafopoulou, X., Steel, C.G.H., **1996a**. The insect neuropeptide prothoracicotropic hormone is released with a dialy rhythm: re-evaluation of its role in development. *Proc. Natl Acad. Sci. USA 93*, 3368–3372; © National Academy of Sciences, USA.)

et al., 2002) and pupal development (**Figure 9a**) (Mizoguchi *et al*., 2001) suggesting clock control of rhythmicity. Rhythmic release of PTTH from the brain is also reported for *Periplaneta* (Richter, 2001). The first of the daily peaks in the fifth instar of *Bombyx* was found to be sensitive to phase shifts of the light : dark (LD) cycle (Mizoguchi *et al*., 2002).

Rhythmicity in release of PTTH may be widespread in insects. An anatomically comparable system of clock neurons is seen in *Drosophila*. The lateral neurons are the principle circadian locus in *Drosophila* (see Section 3.11.3.1); their terminal arborizations in the protocerebrum overlap extensively with a pair of neurons that innervate the part of the ring gland that corresponds to the PGs (**Figure 3**) (Siegmund and Korge, 2001). This pair of neurons (PG-LP neurons in **Figure 3**) resembles the PTTH neurons seen in moths in terms of position, number of cells, the dense collateral fibers along the axon, and the contralateral projection pattern (for details, see Siegmund and Korge (2001) and Section 3.11.3.1), suggesting that the neuronal system for clock control of PTTH is probably also present in *Drosophila*. These presumed PTTH neurons of *Drosophila* make direct contact with the PG cells in the ring gland (**Figure 3**) (see Section 3.11.3.1). Therefore, it is possible that PTTH in *Drosophila* may function as a neurotransmitter or neuromodulator rather than a hormone. Notwithstanding this difference, an essential common feature in all insects examined is the close proximity of clock neurons to the PTTH cells. Control of PTTH release by clock cells in the brains of both hemimetabolous and holometabolous insects suggests that circadian control of PTTH release appears to be conserved among insects and represents a unifying feature in the regulation of PTTH release. It should be noted that this arrangement of neuronal circadian oscillators in the brain and their control of rhythmic release of neuropeptide hormones is found in the SCN of vertebrates (see Section 3.11.3.2).

The continuous rhythmic release of PTTH throughout development implies that the function of PTTH is not merely to activate the PGs at the HCP. Classical studies interpreted the HCP as the only time when PTTH was released, but this view is questioned by many authors (see Section 3.11.4.1.1) The studies above show that PTTH is indeed released at the HCP but this release is only the first of many daily releases. In fact, the greatest quantities of PTTH are released after the HCP. As shown below (see Section 3.11.4.1.3), the circadian rhythm of PTTH appears to play a central role

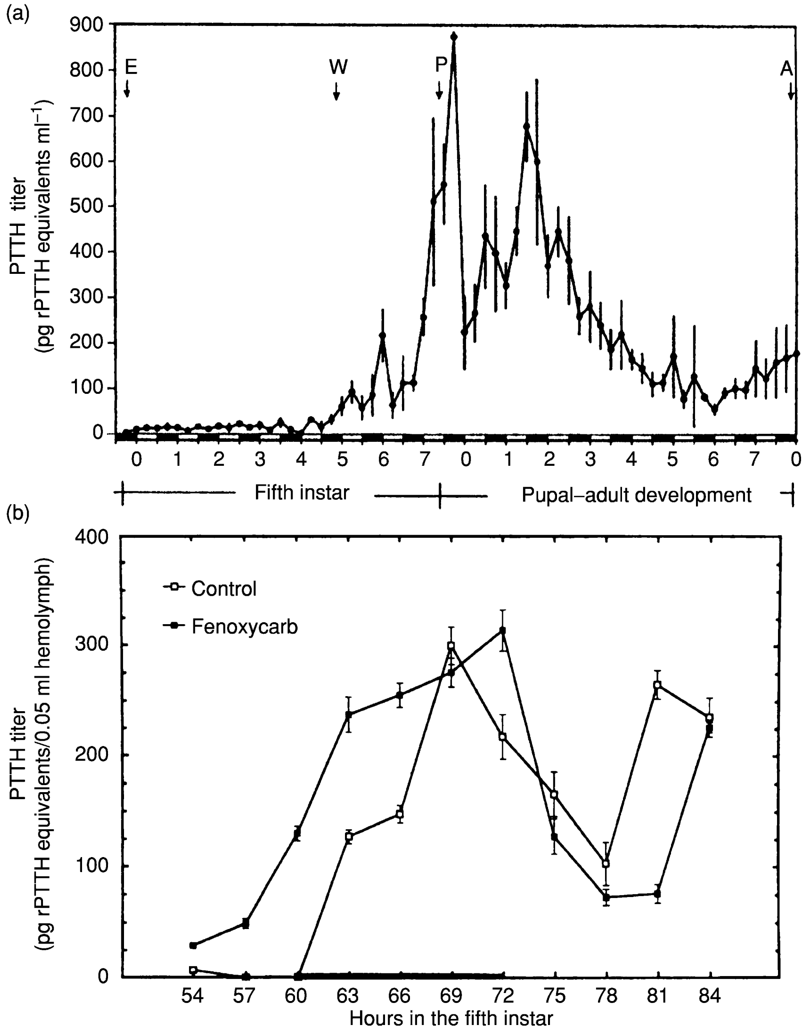

Figure 9 Daily rhythms in PTTH level in the hemolymph of *Bombyx mori*: (a) during the fifth larval instar and pupal–adult development, and (b) during a day of the fifth instar larva. Both patterns of rhythmicity show highs during the scotophase and lows during the photophase. (Reprinted with permission from (a) Mizoguchi, A., Dedos, S.G., Fugo, H., Kataoka, H., **2002**. in the circadian organization of larval development and possibly also of reproductive processes in adults.

3.11.4.1.3. Molting hormones Ecdysteroids are major integrators of development affecting numerous physiological processes (see **Chapters 3.3** and **3.5**). Virtually all cells in the body are exposed to and respond to changes in titer of hemolymph ecdysteroids during development. Expression of genes during specific times of development is firmly understood to be a consequence of these changes in the titer of ecdysteroids. Equivalent actions of ecdysteroids appear to operate on the circadian timescale. Circadian modulation of the ecdysteroid titer appears to provide a temporal framework upon which all the ecdysteroid-responsive cells receive information concerning the time of the day. Ecdysteroids could thus aid in the organization of gene expression within a circadian cycle. Further, all tissues are exposed to the same temporal changes in ecdysteroid levels, providing a mechanism that synchronizes and coordinates gene expression in anatomically distant tissues. In this sense, ecdysteroids can act as internal Zeitgebers conveying time information to diverse developing cells and tissues. This recently formulated capacity of ecdysteroids to act as messengers of time has led to numerous studies concerning clock regulation of ecdysteroid production.

In the early 1980s, the presence of a circadian clock in the PGs of *S. cynthia* was proposed on the basis of a series of ingenious but indirect *in vivo* experiments (Mizoguchi and Ishizaki, 1982, 1984a, 1984b). The phenomenon studied was gut purge, a behavioral change at the end of the feeding, when the larva expels the contents from its gut in preparation for pupation. Gut purge is a gated phenomenon i.e., a population rhythm (Fujishita *et al.*, 1982). The gut purge rhythm free-ran in DD, was abolished in LL, and responded to light pulses (Mizoguchi and Ishizaki, 1984b). Light pulses of 15 min yielded a Type 0 phase response curve (PRC), which showed that gut purge was controlled by a circadian clock. Fujishita *et al.* (1982) associated gut purge with a small, transient increase in the hemolymph ecdysteroid titer. This ecdysteroid peak was phase shifted by light pulses in parallel with phase shifts in gut purge (Mizoguchi and Ishizaki, 1984a). Similar phase shifts in ecdysteroids were obtained in decapitated larvae, emphasizing that the brain was not required for phase-shifting. Gut purge was not monitored in these experiments because it was severely disrupted by decapitation. In the following experiments, the timing of gut purge was employed as an indicator of the timing of ecdysteroid secretion, even though it is not certain that the ecdysteroid increase is the cause of gut purge. Larvae from DD were inserted into holes in light-tight partitions, with the partition located at various different points along the larva in different experiments (Mizoguchi and Ishizaki, 1982). Thus, selected parts of the body could be exposed to 15 min light pulses, while the rest of the body remained in darkness (**Figure 10**). When the whole larva was illuminated, the timing of gut purge was phase-delayed. A phase delay was not observed when only the head and prothorax were illuminated, but a phase delay became evident when the mesothorax and metathorax were also illuminated. Full phase delay resulted when both the head and the whole thorax were illuminated. These experiments implicated a thoracic center (presumably the PGs) in the control of the timing of gut purge. In another experiment, three pairs of PGs were transplanted into the abdomens of intact larvae which were then transferred to DD and given 10 s light pulses to various parts of the body, i.e., anterior (brain and intrinsic PGs), posterior (implanted PGs), or whole body (**Figure 10**). Invariably, the time of gut purge was dictated by the implanted PGs. The authors assumed that the phase shifts in the time of gut purge were due to hase shifts in the time of the ecdysteroid rise. It was concluded that the PGs possessed a photosensitive circadian clock. However, these ingenious

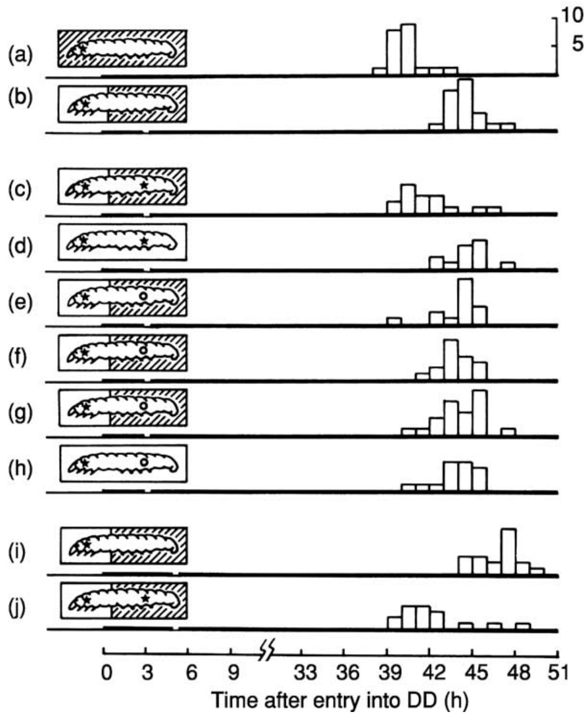

Figure 10 Effects of light pulses on the phase of gut purge of *Bombyx* larvae with and without implants of various organs in the abdomen. Larvae were transferred to DD after implantation and were given 10 s light pulses to various body parts. Pulses of light were administered 3 h (a–h) or 5 h (i and j) after transfer to DD. Clear areas on the diagrams of larvae on the left show the body areas that were illuminated. Histograms on the right show the time of gut purge. Asterisk denotes implanted prothoracic glands (PGs) and open circles other transplanted organs; (e) and (h) three brains; (f) three mesothoracic ganglia; (g) fat body. (a) Control; larvae in DD without implanted PGs and not exposed to light pulse. (b) Illumination of the head and thorax (intrinsic PGs) causes phase delay in gut purge. (c) Light pulse to anterior part of the body of a larvae with three pairs of PGs implanted (implanted PGs in dark, intrinsic PGs in light) does not phase-shift gut purge (compare c with b). (d) Whole body illumination of larvae with both sets of PGs causes phase delay. (e–h) Transplantation of various other tissues and illumination of either the anterior or the whole body of host delays gut purge as in (b). Light pulses given 5 h after transfer to DD produce similar results as those given 3 h after transfer (compare i, j with b, c). (Reproduced with permission from Mizoguchi, A., Ishizaki, H., **1982**. Prothoracic glands of the saturniid moth *Samia cynthia ricini* possess a circadian clock controlling gut purge timing. *Proc. Natl Acad. Sci. USA 79*, 2726–2730; © National Academy of Sciences, USA.)

experiments are difficult to interpret. For example, both the implanted and intrinsic PGs were presumably receiving daily stimulation from PTTH (see Section 3.11.4.1.2) and the four pairs of PGs would doubtlessly interact both with each other and with PTTH from the brain in ways that cannot be predicted (Steel and Davey, 1985).

Clear evidence that a circadian clock controls ecdysteroid levels in the hemolymph was reported

for *Rhodnius* (Steel and Ampleford, 1984; Ampleford and Steel, 1985). In *Rhodnius*, the hemolymph ecdysteroid titer during the week preceding ecdysis to the adult displays a strong daily rhythm with a massive daily peak during each scotophase and a deep trough during each photophase (**Figure 11**). The rhythm is controlled by a circadian clock since it free-runs in aperiodic conditions (e.g., DD) with a period length that is temperature compensated. The rhythm is seen throughout larval–adult development (Vafopoulou and Steel, 1989, 1991). The daily scotophase peaks in titer are three to five times higher than the values seen in adjacent photophases. It was suggested that the daily rhythm of ecdysteroid titer probably involved both synthetic (see below) and catabolic rhythmicities. Indeed, the daily decrease in titer from the top of the scotophase peak to the bottom of the photophase trough was equal to the daily amount of ecdysteroids excreted in the feces. The removal of ecdysteroids from the hemolymph was assumed to be accomplished by a combination of conjugation, sequestration in the tissues, and excretion via the Malpighian tubules and possibly also the midgut (Steel and Ampleford, 1984).

Subsequently, rhythmicities in hemolymph ecdysteroid titers were also unraveled in various other insects. In the wax moth, *Galleria mellonella*, a circadian rhythm in the titer was seen in the last larval instar (Cymborowski *et al.*, 1989). The rhythm was also present in decapitated animals emphasizing that expression of the rhythm did not require the presence of the head (Cymborowski *et al.*, 1991). Daily rhythms in ecdysteroid titer were found in both larvae and pupae of *Bombyx* (Sakurai *et al.*, 1998; Mizoguchi *et al.*, 2001, 2002). In larvae of *Manduca*, the titer displays a series of daily "steps" (Schwartz and Truman, 1983). A daily rhythm was also seen in larvae of *Periplaneta* (Richter, 2001).

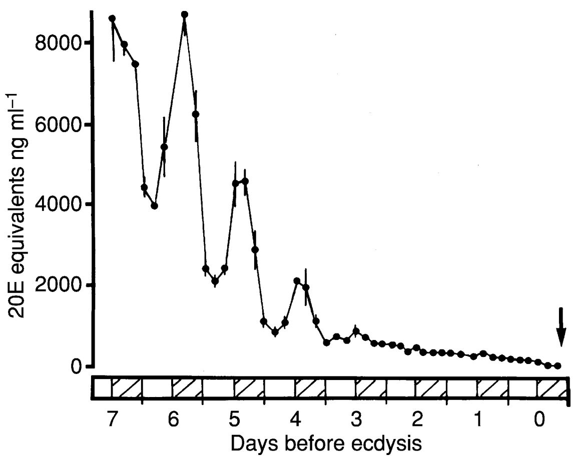

Figure 11 Rhythm of hemolymph ecdysteroid titer during larval–adult development of *Rhodnius*. Cross-hatched areas indicate scotophases and clear areas indicate photophases. Arrow marks time of ecdysis to the adult. Massive daily peaks in ecdysteroid titer occur during each scotophase. (Reprinted with permission from Ampleford, E.J., Steel, C.G.H., **1985**. Circadian control of a daily rhythm in hemolymph ecdysteroid titer in the insect *Rhodnius prolixus* (Hemiptera). *Gen. Comp. Endocrinol. 59*, 453–459; © Elsevier.)

The pronounced rhythmicity in the hemolymph ecdysteroid titer of *Rhodnius* implied the existence of an underlying rhythmicity in synthesis. Subsequent experiments focused on the timed ecdysteroid synthesis by the PGs. Synthesis of ecdysteroids was studied *in vitro* following explantation of PGs every 4–5 h for many days during larval–adult development (Vafopoulou and Steel, 1991). Ecdysteroids are not stored within the PG cells, thus the rate of ecdysteroid release equals the rate of synthesis (Vafopoulou and Steel, 1989). The titer of hemolymph ecdysteroids was measured for all donors of PGs, enabling the synthesis by PGs *in vitro* to be correlated with the hemolymph titer of the same animals *in vivo*. A daily rhythm of ecdysteroid synthesis was seen that was synchronous with the hemolymph titer *in vivo*. Synthesis in the scotophase was three to five times higher than synthesis in the photophase. The synthesis rhythm free-ran in both DD and LL and was temperature compensated. Therefore, the PGs contain a circadian clock. Ecdysteroid synthesis by PGs *in vitro* showed acceleration when the PGs were transferred from LL to DD *in vitro* (Vafopoulou and Steel, 1992). This finding showed that ecdysteroid synthesis by PGs was directly photosensitive and suggested that the clock controlling synthesis might also be photosensitive. Daily rhythms in ecdysteroid synthesis have also been observed in *Galleria* (Cymborowski *et al.*, 1991), *Bombyx* (Sakurai *et al.*, 1998), and *Periplaneta* (Richter, 2001).

In *Rhodnius*, the underlying complexity of this clock began to emerge when it was found that the phase of the oscillations in synthesis differs depending on whether the animals were transferred to DD or LL (Vafopoulou and Steel, 1991). In animals that were transferred from 12 : 12 to DD, the rhythm of ecdysteroid synthesis by PGs free-ran with a phase similar to the entrained state. But transfer to LL resulted in abolition of the rhythm for one cycle; then the rhythm reemerged abruptly and free-ran with peaks in the subjective photophase, i.e., the rhythm in LL free-runs in antiphase to that in DD or the entrained state. The period length in LL was slightly shorter than that in the entrained state or DD. The hemolymph titer of animals transferred to LL also undergoes the same abrupt phase inversion

after a lag of one cycle. Period length and phase of a free-running rhythm are expressions of the underlying oscillator that regulates them. The differential behavior of the rhythm in DD and LL was the first indication that more than one oscillator is responsible for driving the overt rhythm of ecdysteroid synthesis. One oscillator is phase-set by lights-off, free-runs in DD, and has a period length of about 24 h. The other oscillator is phase-set by lights-on, free-runs in LL, and has a period length of less than 24 h. Apparently, the clock mechanism underlying the *Rhodnius* rhythm is complex and consists of several components. In order to dissect the components of this clock it was necessary to adopt entirely *in vitro* approaches that would eliminate hormonal influences on PGs. Rhythmic ecdysteroid synthesis persists for 42 h *in vitro* by explanted PGs in the absence of light cues (Vafopoulou and Steel, 1998). While these observations demonstrate that the PGs synthesize ecdysteroids rhythmically entirely *in vitro*, they do not exclude the possibility that this rhythm had been established by inputs received by the PGs *in vivo* and whose effects persisted for several cycles *in vitro*. Definitive demonstration that the PGs possess a photosensitive circadian oscillator came from the induction of rhythmicity in synthesis *in vitro* by light signals in PGs that were arrhythmic (Vafopoulou and Steel, 1998). Explanted PGs from arrhythmic LL animals were transferred *in vitro* to DD and ecdysteroid synthesis monitored every 3–4 h for 42 h (**Figure 12**). These glands responded to the transfer to DD signal with the sharp acceleration of synthesis reported in 1992 but also initiated a free-running circadian rhythm of ecdysteroid synthesis entirely *in vitro*. Therefore, the PGs possess a photosensitive circadian clock that regulates rhythmic ecdysteroid synthesis. This rhythmic synthesis drives the upward side of the hemolymph titer rhythm every day. Thus, the PGs meet all the criteria that classify them as endocrine clocks. These findings confirm and extend the PG clock model first invoked by Mizoguchi and Ishizaki (1982) in *Samia*. A PG clock was also invoked in *Galleria* where decapitations of larvae did not affect the rhythm of hemolymph ecdysteroids (Cymborowski *et al.*, 1991). In contrast, neck ligation in *Periplaneta* larvae severely depressed ecdysteroid synthesis to such an extent that no rhythm was detectable (Richter, 2001). In *Bombyx*, it is still unclear whether the rhythm of hemolymph ecdysteroids (Sakurai *et al.*, 1998; Mizoguchi *et al.*, 2001) is driven by the PTTH rhythm (Mizoguchi *et al.*, 2001) or by the PG clock proposed earlier in *Samia* by Mizoguchi and Ishizaki (1982). In *Drosophila* there is good evidence that the PG cells of the ring gland possess an endogenous circadian clock (Emery *et al.*, 1997) but its function is unknown. Expression of the *per* gene exhibits a daily rhythm in the region of the ring gland that corresponds to the PG. The rhythm of *per* expression is entrained by light *in vitro* in incubations of the ring gland attached to the CNS. Addition of tetrodotoxin (TTX) to the incubation medium at concentrations sufficient to inhibit nerve conduction did not affect the *per* rhythm, demonstrating that the rhythm was not driven by the nervous system but was controlled locally by the PG cells. However, there is no evidence of rhythmic ecdysteroid synthesis by these cells, nor is rhythmicity evident in any of the numerous publications on *Drosophila* ecdysteroid titers (Richards, 1981). Therefore, in *Drosophila*, the function of this PG clock is unclear.

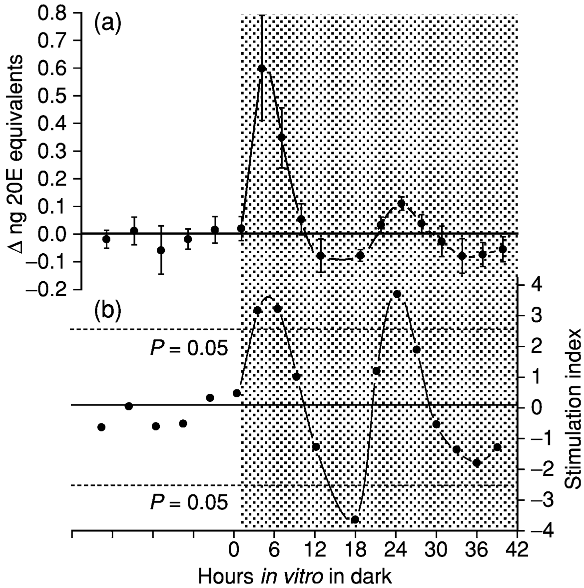

Figure 12 *In vitro* induction of rhythmic ecdysteroid synthesis by *Rhodnius* PGs following transfer from LL (clear area) to DD (stippled area). (a) Glands in LL are clearly arrhythmic (points in clear area), but become rhythmic on transfer to DD. The period length of the induced oscillations is close to 24 h. Lower panel (b) shows the statistical significance of the actual values in the upper panel (a). (Reproduced with permission from Vafopoulou, X., Steel, C.G.H. **1998**. A photosensitive circadian oscillator in an insect endocrine gland: photic induction of rhythmic steroidogenesis *in vitro*. *J. Comp. Physiol. A* 182, 343–349; © Springer-Verlag.)

PGs comprise an ultrastructurally uniform population of about 200 cells (Beaulaton *et al.*, 1984; Dai *et al.*, 1994), which exhibit action potentials and are electrically coupled (Eusebio and Moody, 1986) by gap junctions (Dai *et al.*, 1994). Synchrony of the whole gland would therefore result from mutual coupling between its component cells. Each PG cell, when dissociated from the whole, appears

capable of synthesizing ecdysteroids (Smith *et al*., 1986; Asahina *et al*., 1994). The PG cells in *Rhodnius* do not receive any nerve supply (Wigglesworth, 1952) by which the cells might be synchronized, whereas those in at least some Lepidoptera are richly innervated (Lee, 1948). There is evidence that all the cells of the paired PGs of *Rhodnius* are circadian oscillators. All the cells show immunoreactivity to antibodies against the clock proteins PER and TIM (**Figure 13**) (Terry and Steel, 2004) and these proteins exhibit robust circadian cycling in abundance and nuclear migration which free-runs in DD; strong immunolocalization to the nucleus occurs during the scotophase whereas the cells are almost devoid of stain during the photophase. Therefore, each PG is a group of cellular oscillators that function in unison as a result of cellular coupling. The construction of a clock from individual cellular oscillators coupled by gap junctions and local potentials is also seen in neuronal clocks in molluscs (Block *et al*., 1993) and the mammalian SCN. Thus the PG clock, though an endocrine gland, is remarkably similar to neuronal clocks. It is of interest that PGs (at least in *Bombyx*) are, like the nervous system, of ectodermal origin (Lee, 1948).

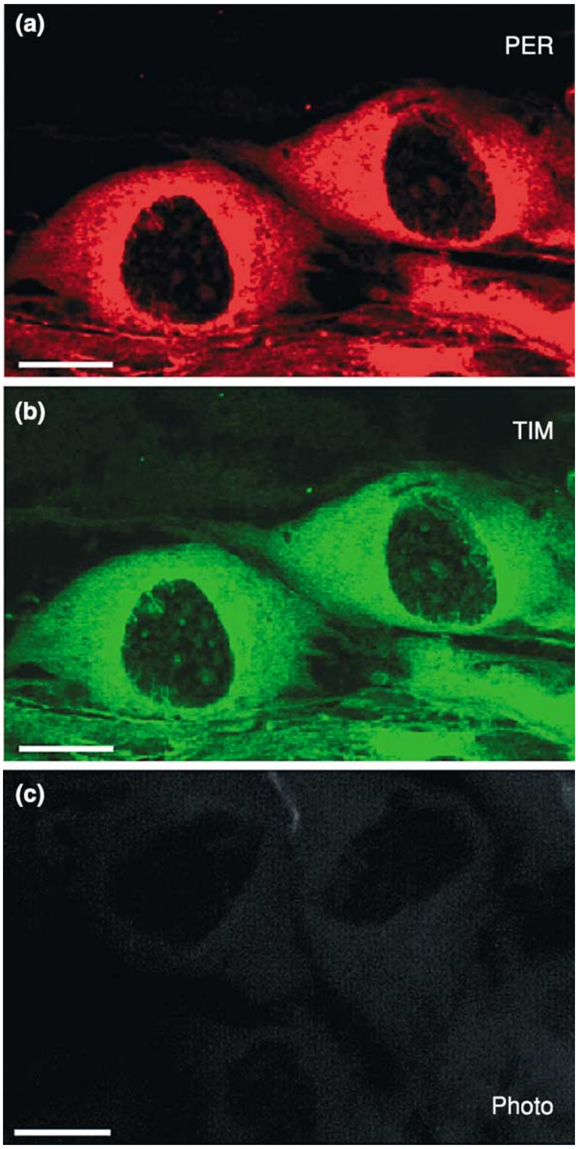

Figure 13 PER (a, red) and TIM (b, green) are colocalized in PG cells of *Rhodnius* and also show cycling. During the scotophase (a, b) immunoreactivity is high in the cytoplasm but some is also seen in the nucleus. During the photophase (c), immunoreactivity is minimal. *Rhodnius* PGs synthesize ecdysteroids during the scotophase but not during the photophase. Scale bar = 30 μm.

The rhythms of both ecdysteroid synthesis and hemolymph titer *in vivo* occur in the presence of a PTTH rhythm (see Section 3.11.4.1.2). Since the PGs are the only known targets of PTTH in larvae, it is expected that PTTH would affect the function of the PGs. However, as shown above, the PGs possess their own photosensitive clock and this does not support the possibility that the rhythmicity in synthesis *in vivo* is driven by rhythmic PTTH. The functional relationship between the PTTH clock in the brain and the PG clock was investigated by decapitation or paralysis with TTX of whole *Rhodnius* larvae in order to reveal the properties of the rhythm of ecdysteroid synthesis in the absence of rhythmic neuropeptide input (Pelc and Steel, 1997). TTX was used at a sublethal dose that caused flaccid paralysis of the whole animal and prevented release of PTTH for 4 days. Rhythmicity was maintained in both ecdysteroid synthesis and the hemolymph ecdysteroid titer; the rhythms retained entrainment to LD cycles and free-ran in both DD and LL. The rhythms showed no evidence of damping or loss of entrainment, confirming that the PG clock described *in vitro* is operative *in vivo*. This finding probably explains why decapitation (after the HCP) does not arrest development; the rhythmicity in hemolymph ecdysteroids is maintained by the PG clock, which becomes directly entrained to light in headless animals. Therefore, rhythmic neuropeptide input is not required to drive rhythmic steroidogenesis by the PGs *in vivo*. This conclusion contrasts with comparable systems in vertebrates, where rhythms in steroidogenesis are regarded as passive slaves driven by rhythmic neuropeptide input (see Turek, 1994). An important finding was that in both decapitated and TTX-paralyzed animals the rhythms of synthesis and titer always adopted a phase 12 h different from those seen when PTTH was present, regardless of the conditions of illumination. Therefore, the rhythm of steroidogenesis adopted a daytime peak

when entrained to light *in vivo* in paralyzed animals (no PTTH), but adopted a night-time peak when PTTH was present (normal animals). It was concluded that in intact animals, PTTH is the dominant entraining agent to the PG clock; photic entrainment of steroidogenesis is revealed only when rhythmic PTTH input is removed. In the presence of both light and PTTH the PGs entrain preferentially to PTTH. Thus, both light and PTTH act as Zeitgebers to the PG clock, but they contradict rather than reinforce each other. There are several examples in the literature in which circadian systems can be entrained by both light and neurochemical agents. Examples include neuropeptide Y (Yannielli and Harrington, 2000; Maywood *et al*., 2002) and melatonin (Lewy *et al*., 1995) actions on the mammalian circadian system and the action of serotonin on the circadian system in the eye of the mollusc *Aplysia californica* (Corrent *et al*., 1982; Block *et al*., 1993) and in the optic lobe of *Gryllus bimaculatus* (Saifullah and Tomioka, 2003).

The function of PTTH as an entraining agent to the PG clock shows that PTTH can act on the clock, not just on the pathway of steroidogenesis. But PTTH action on the clock could be mediated by the same intracellular pathway by which PTTH mediates stimulation of steroidogenesis. In *Manduca*, PTTH regulates calcium influx into the PG cells, which leads to stimulation of calmodulin-sensitive adenylate cyclase in the PGs (Gilbert *et al*., 2002) (see **Chapter 3.2**). Calcium and cAMP are known to induce phase shifts in many circadian systems; they act directly on the clock in the SCN (Tischkau *et al*., 2003) and frequently produce PRCs which are 12 h displaced from the PRCs for light pulses (Edmunds, 1988). Therefore, this signal transduction pathway is an appropriate pathway by which PTTH could regulate the PG clock.

The information above indicates that both PTTH and ecdysteroids are regulated by photosensitive circadian oscillators and their circadian rhythms interact every day. It is now evident that these two hormones do not act consecutively in a "cascade" but are continuously integrated together into a daily "tango" throughout the course of development (Steel and Vafopoulou, 1999) (see Section 3.11.4.1.4).

3.11.4.1.4. Hormones as agents that couple clocks The preceding sections have documented that the circadian system of *Rhodnius*, and probably that of other insects, consists of multiple photosensitive clocks coupled to the neuroendocrine axis. Two of these clocks are found in the brain where they are located in two symmetrical groups of neurons in the dorsal protocerebrum that control rhythmic release of PTTH. Coupling of the left and right clocks in the brain to each other is probably achieved by neural connections across the midline as is the case with the paired optic lobe clocks (**Figure 2**). Each PG is also a photosensitive clock that generates rhythmicity in ecdysteroid synthesis. All cells of each PG appear to be cellular oscillators since they all exhibit circadian cycling of PER/TIM clock proteins and are coupled into a functional unit by cell junctions. Thus, the circadian system that drives the downstream rhythm of the hemolymph ecdysteroid titer consists of (at least) four anatomically discrete, photosensitive clocks. Four similar clock loci, but less fully documented, are seen in moths where the information is distributed between the three genera, *Bombyx*, *Antheraea*, and *Samia*. In *Drosophila*, the number of loci is reduced to three because the normally paired PGs are fused into one ring gland. Close association between clock cells in the brain and PTTH cells is seen in the three divergent genera, *Drosophila*, *Antheraea*, and *Rhodnius*. The situation in insects therefore, is similar to the one seen in vertebrates where overt hormone rhythms express the output of multiple coupled clocks. The intricacy of functional coordination of the four (or three) circadian clocks in whole animals was studied in *Rhodnius in vivo* (Vafopoulou and Steel, 2001). PTTH release ceased completely after a few cycles in animals maintained in LL; free-running rhythmic release was promptly initiated by transfer to DD, demonstrating that the circadian oscillators that control PTTH rhythmicity are photosensitive. Transfer to DD also initiated a free-running rhythm of ecdysteroid synthesis in spite of the thick, brown overlying cuticle. Interestingly, the first initiated peak of steroidogenesis occurred several hours *prior* to the first peak of PTTH release and was not impaired when PTTH release was prevented by prior injections of TTX. These findings suggested that the initial response to a light cue involves direct response of the PG clocks to light. However, in intact animals, the second peak of steroidogenesis becomes phase-delayed until it synchronizes with the rhythm of PTTH release. Thus, the PTTH rhythm free-ran with a stable period and phase following its initiation, whereas the ecdysteroid rhythm became shifted by PTTH after its initiation. This experiment clearly showed that both clocks in brain and PGs operate *in vivo* and can initiate rhythmicity in their respective hormones following the same light cue. However, when the PTTH rhythm is present, it overrides light as a Zeitgeber to PGs and phase-sets the PG clocks. The neuropeptide therefore acts as an entraining agent for the PG clocks in whole animals

and conveys temporal information to them. Therefore, in *Rhodnius*, and probably in other insects as well, PTTH acts as a hormonal Zeitgeber to the PGs. This action synchronizes the PTTH clocks and PG clocks together into a functional unit. Therefore, the function of PTTH is integral to the circadian organization of the endocrine system.

It has been shown that the PGs are able to recognize the daily time-cues from the PTTH rhythm (Vafopoulou and Steel, 1999). Treatment of entrained PGs of *Rhodnius* with PTTH *in vitro* leads to an augmentation of ecdysteroid synthesis, but only in PGs taken from animals at certain times of the day; PGs are maximally responsive to PTTH around lights-off and insensitive to PTTH around lights-on. Therefore, PGs exhibit a daily rhythm of responsiveness to PTTH, which implies the existence of a daily up- and downregulation of PTTH receptor availability. It is interesting that the rhythm of responsiveness phase-leads that of PTTH release. Whether the responsiveness rhythm is driven by the PTTH rhythm or is endogenously controlled by the PGs themselves is not known at present. The ability of PTTH to set the phase of the PG clock (discussed above) shows that it is able to act on the clock, not just on steroidogenesis. Thus, the brain clocks communicate daily with the PG clocks.

It is probable that this communication is reciprocal, with ecdysteroids providing daily information to the brain. Feedback actions of ecdysteroids on PTTH release by the brain is cited frequently in the literature (see **Chapter 3.8**), but has not been studied from a circadian perspective. Nevertheless, it is well known that the nervous system is a major target for the action of ecdysteroids (see **Chapter 2.4**). It is possible that the rhythm of ecdysteroids acts on the clock cells in the brain or on brain neurons that provide input to the clock cells, leading to affects on PTTH release. Indeed, studies of ecdysteroid receptors (EcR) in *Rhodnius* (Vafopoulou *et al.*, 2001, 2004a) using immunohistochemistry revealed the presence of EcR in all of the 17 medial neurosecretory cells of the protocerebrum as well as the dorsal and lateral clock cells. Moreover, nuclear EcR exhibits cycling in all three locations. In the dorsal (**Figure 14**) as well as the lateral regions of the brain, EcR immunobinding exhibits cycling between subcellular locations within a day; immunobinding is exclusively nuclear during scotophase (**Figure 14a**) and exclusively cytoplasmic during photophase (**Figure 14b**). Therefore, there are several pathways by which ecdysteroids could provide inputs to the brain clocks. Unlike EcR in epidermal cells, which cycles in synchrony with the hemolymph ecdysteroid rhythm, the rhythm of nuclear EcR in the brain is many hours out of synchrony with both the hemolymph ecdysteroid rhythm and the EcR rhythm in epidermal cells. These findings are consistent with the reported induction of EcR in epidermal cells by ecdysteroids, but argue against direct induction of EcR in brain neurons by ecdysteroids, raising the prospect of more complex action of ecdysteroids on the brain (Vafopoulou *et al.*, 2004a).

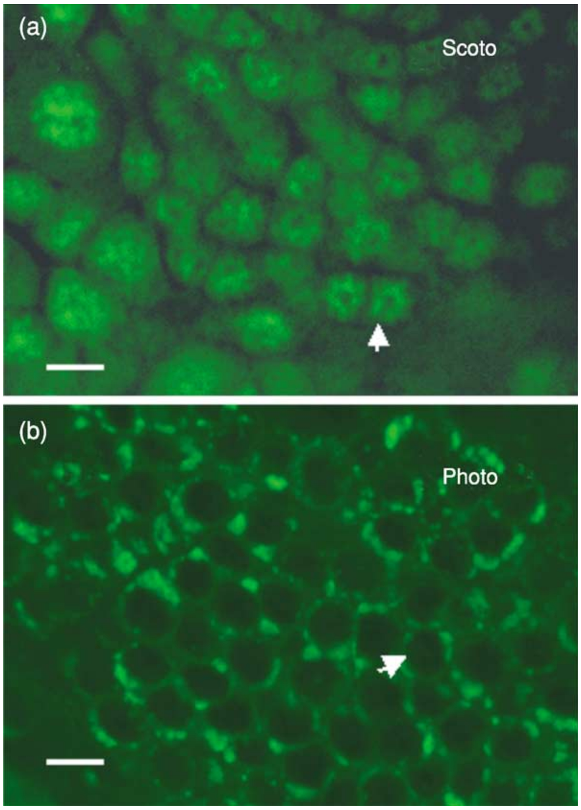

Figure 14 Ecdysteroid receptor (EcR) cycles in the dorsal clock cells (adjacent to the mushroom body) in the protocerebrum of *Rhodnius*. (a) EcR immunoreactivity is abundant and confined to nuclei during the scotophase. (b) During the photophase, EcR is confined to the cytoplasm. Arrows indicate nuclei. Scale bar = 12 μm.

Yet another endocrine component of the multi-oscillator circadian system may be melatonin. Melatonin has been detected in tissue extracts of several species (Vivien-Roels and Pevet, 1993; Hardeland and Poeggeler, 2003) including hemolymph (Itoh *et al.*, 1995a, 1995b; Linn *et al.*, 1995) where changes in levels within a day have been reported. To date, true circadian studies have been conducted only in *Rhodnius* (Gorbet and Steel, 2003, 2004). A robust daily rhythm in hemolymph levels has been found, with peaks in the scotophase and minimal values in the photophase (as commonly seen in vertebrates) (**Figure 15**). The melatonin rhythm is

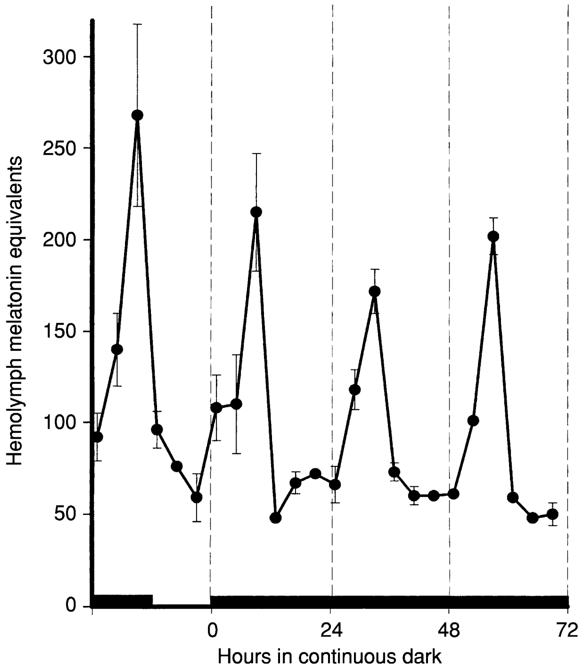

Figure 15 Rhythm of melatonin in the hemolymph of *Rhodnius*. Entrained rhythm in 12 : 12 (first peak) peaks in the late scotophase and free-runs in DD for at least three cycles (dark bar), illustrating circadian control of the rhythm.

controlled by a circadian clock since it free-runs in DD and damps out after three cycles in LL. The rhythmic pattern and the daily peak levels of melatonin in *Rhodnius* are very similar to those seen in circulating melatonin in vertebrate blood (Gorbet and Steel, 2003). Melatonin is known to act on steroidogenic tissues in vertebrates where it influences the phase of steroid release (Pang *et al.*, 1998). Melatonin may therefore participate in the circadian regulation of the PTTH–ecdysteroid neuroendocrine axis. In *Periplaneta*, no effect of melatonin on ecdysteroid synthesis by the PGs was detected, but it appears to facilitate the release of PTTH from brains *in vitro* (Richter *et al.*, 2000). It is possible that rhythmic levels of melatonin in the *Rhodnius* hemolymph modulate rhythmic release of PTTH by the brain by acting on some component of the PTTH clock in the brain. Such an arrangement would be strikingly analogous to mammalian systems, where melatonin modulates the phase of clock neurons in the SCN (Gillette and McArthur, 1995). Another possible function of melatonin may be to modulate EcR levels in the brain. In mammals, melatonin modulates steroid hormone receptor levels (Roy and Wilson, 1981; Danforth *et al.*, 1983; Molis *et al.*, 1994). Further, many brain regions of mammals exhibit rhythmic electrical activity. Such rhythms are driven by neuronal circadian oscillators in discrete brain loci such as the SCN; these regions can regulate the phase of rhythmic expression of steroid nuclear receptors (van Esseveldt *et al.*, 2000). The neuronal brain oscillators are characterized by the expression of PER/TIM clock proteins. Since two comparable loci of PER/TIM oscillators have been found in the lateral and dorsal regions of the *Rhodnius* brain, this raises the possibility that neuronal rhythms in the brain, and by association rhythms in EcR, could be driven from within the brain. Thus, there exist several possible mechanisms whereby the phase of EcR rhythmicity in the brain of *Rhodnius* described above may be regulated.

It is concluded that the circadian organization of developmental hormones, at least in *Rhodnius*, is achieved by four circadian clocks located in anatomically distinct sites, two in the brain and one in each PG. They are coupled into a functional unit *in vivo* by nerves within the brain and by hormonal pathways involving PTTH, ecdysteroids, and possibly melatonin (Steel and Vafopoulou, 2001). It should be noted that we are portraying these hormones as agents that communicate temporal information between circadian oscillators. This portrayal is still novel for insect hormones although it is well established in mammalian systems (Reppert and Weaver, 2001; Balsalobre, 2002; Kalsbeek and Buijs, 2002).

The output of the above complex circadian system is the circadian rhythm of hemolymph ecdysteroids. Diverse cells and tissues of the developing organism are thereby exposed to a tightly regulated sequence of increases and decreases in ecdysteroid titer on a circadian timescale. Do cells respond to these daily changes in hormone levels? Apparently they do. EcR is found in many target tissues; among them, the epidermis is a primary target of ecdysteroid action and EcR in epidermal cells is well studied (see **Chapter 3.5**). In *Rhodnius*, the relative abundance of nuclear EcR immunoreactivity in epidermal cells shows a striking daily rhythm that is synchronous with the rhythm of ecdysteroids in the hemolymph (Vafopoulou *et al.*, 2001, 2004a). These close temporal relations between hormone and EcR cycling are indicative of the regulation of EcR expression by the levels of circulating ecdysteroids (see **Chapter 3.5**). Indeed when hormonally naive epidermal cells of a *Chironomus* cell line are exposed to 20E, EcR immunoreactivity disappears from the cytoplasm and increases in the nucleus (Lammerding-Köppel *et al.*, 1998). These findings further indicate that the circadian time signals embedded in the rhythmic

ecdysteroid titer are detected by the primary target cells of the hormone, i.e., the epidermis.

This complexity of the multioscillator system in *Rhodnius* and its control over the rhythmicity of hormones is shown in **Figure 16**. Since most insect cells possess ecdysteroid-responsive genes which are known to be expressed in temporally orchestrated sequences during the course of development (Riddiford *et al*., 2000; Thummel, 2002) (see **Chapter 3.5**), it is possible that the rhythm in hemolymph ecdysteroids also orchestrates sequential gene expression in target cells within the circadian cycle. A case in point is the transcriptional activity of region I-18C of the salivary gland polytene chromosomes of the midge *Chironomus tentans* (Lezzi *et al*., 1991). This chromosomal region exhibits a daily rhythm of condensation and decondensation (associated with transcriptional activity). Decondensation occurs during the scotophase and parallels increased responsiveness to exogenous 20-hydroxyecdysone (20E).

Since most cells in an organism lack mechanisms which enable them to measure time or to synchronize themselves with the environment, the circadian system above appears to be the primary mechanism that maintains internal temporal organization during development both in the insect as a whole and within cells. Since all the hormones in the circadian system persist into the adult stage (see Section 3.11.5.1), it is possible that they constitute a central timing system throughout life.

3.11.4.2. Rhythmicity in Cuticle Deposition

In many insects, new cuticle is deposited in morphologically visible "daily growth layers." Such daily layers are found in all instars of many hemimetabolous insects and in the adults of various holometabolous species (Neville, 1983). In many species, this daily rhythm is under circadian control (Neville, 1965). These early reports demonstrate that epidermal cells exhibit circadian rhythmicity. Since the activities of epidermal cells are regulated primarily by ecdysteroids, the possibility is raised that daily growth layers in cuticle are driven by rhythms in ecdysteroids, or perhaps other hormones. The literature on daily growth layers does not address this possibility since it largely predates the discovery of rhythmicity in the endocrine system. This literature is briefly revisited below. It is suggested that daily growth layers may reflect rhythmicity in epidermal cells that is driven by ecdysteroids or other hormones (see **Chapters 4.2–4.4**).

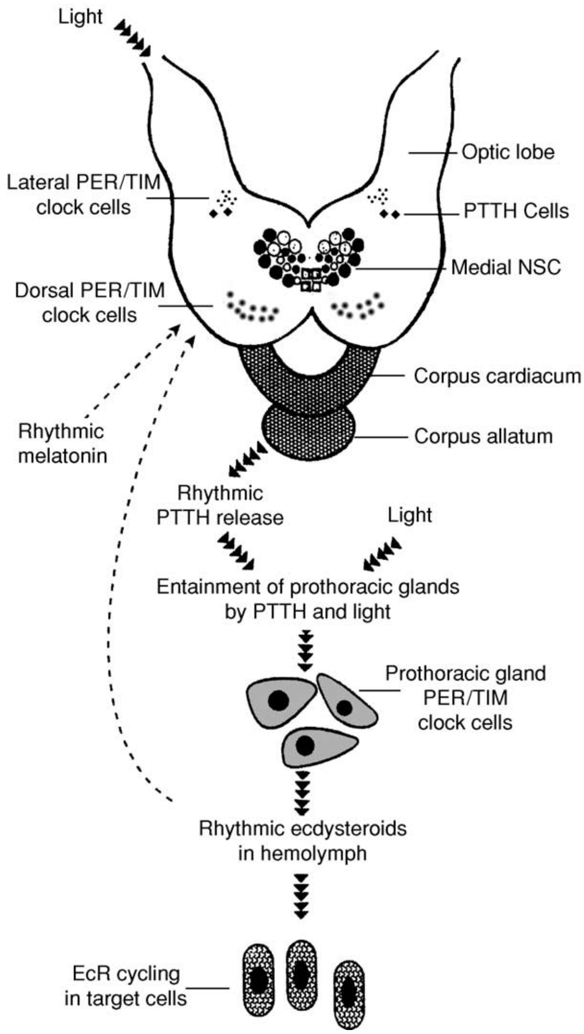

Figure 16 Schematic diagram of circadian regulation of developmental hormones in *Rhodnius*. PTTH is released rhythmically from the retrocerebral complex. The PTTH cells (diamonds) in the brain are adjacent to the lateral group of clock neurons. At least in *Drosophila*, these clock neurons project to the neurosecretory cells of the pars intercerebralis and also interact with the dorsal clock neurons (see **Figure 4**). PTTH acts on the PGs to entrain a PER/TIM-based clock in the PG cells (**Figure 13**) that is directly photosensitive (**Figure 12**). Rhythmicity in ecdysteroid synthesis is generated by the PG clock but is entrained by both PTTH and light. The resulting hemolymph titer of ecdysteroids is rhythmic, and distributes temporal information to target cells. Circadian cycling of EcR occurs in target cells, indicating rhythmic responses to ecdysteroids. The hemolymph ecdysteroid rhythm may act back on the brain (dashed arrow) via cycling EcR in the brain (**Figure 14**). The circadian rhythm of melatonin (**Figure 15**) provides a further possible input into the system. This system contains at least four circadian clocks (two in the brain, one in each PG) that are coupled by nerves and hormones (see text). Ecdysteroids are the primary controlled output of this system, distributing temporal information to all cells that possess EcR. They are potentially able to orchestrate target cell responses within a circadian cycle and to synchronize cells in distant locations with each other.

The first part of the cuticle to be deposited during a molt is a thin epicuticle composed of several layers (Hepburn, 1985). Deposition of epicuticle occurs around the middle of the molt cycle in the presence of peak titers of ecdysteroids. The bulk of the cuticle (procuticle) is deposited during decreasing titers of ecdysteroids. Frequently, by the time of ecdysis only the outer part of procuticle (the future exocuticle) has been secreted. The deposition of procuticle continues after ecdysis and may continue until the next apolysis; this region is usually termed endocuticle. Cuticle consists of chitin microfibrils which are embedded in a matrix of proteins and are laid down as plaques on the surface of the epidermal cells (Neville, 1975). At any particular depth in the cuticle, the microfibrils lie parallel to one another in the plane of the cuticle. However, when viewed from above, the orientation of the microfibrils rotates anticlockwise through successive layers within the cuticle; this arrangement of microfibrils forms a helicoidal pattern between successive levels within the procuticle. A vertical section of this type of procuticle gives the appearance of lamellae because each orientation of microfibrils is seen to repeat every 180° of the helix. Thus, each lamella consists of several layers of microfibrils whose orientation changes progressively with the depth of the cuticle. In many insects, procuticle may be lamellate throughout resulting in endocuticle and exocuticle regions that are morphologically indistinguishable. However, there are many species in which the endocuticle consists of microfibrils arranged in alternating regions of lamellate layers (with helicoidal orientation) and nonlamellate layers (with uniform orientation). In these species, the cuticle normally grows by one pair of these bands each day; for part of the day lamellate cuticle is laid down, and for the rest of the day nonlamellate cuticle is laid down. The physiological mechanism regulating the deposition of endocuticle is largely unknown (Riddiford, 1985). Nevertheless, the presence of these daily growth layers in diverse insect species (Neville, 1983) has spawned interest in the circadian control of cuticle secretion and its implications for rhythmicity in the epidermis and the hormones that regulate cuticle secretion.

There is considerable evidence that daily deposition of alternate layers of lamellate and nonlamellate cuticle is under circadian regulation in a number of insects. In adults of the locusts *Schistocerca gregaria* and *Locusta migratoria*, the daily rhythm of bands in the hind tibia exhibited all the characteristics of an endogenously controlled rhythm; the rhythm free-ran in DD, was abolished in LL, was temperature compensated, and was entrained by light (Neville, 1965). Removal of the eyes and ocelli or painting of the head capsule black or transplantation of cylinders of tibia into the hemocoel of imaginal hosts did not affect the cuticle rhythm in locusts (Neville, 1967). These experiments demonstrated that rhythmic cuticle deposition was independent of organized photoreceptors and did not require nervous regulation. The results are consistent with the possibility that rhythmic cuticle secretion is sustained by rhythmic humoral factors in the hemolymph. However, the cuticle rhythm in cockroaches such as *Blaberus cranifer* and *L. maderae*, exhibits many of the characteristics of circadian regulation (temperature compensation, for example) (Wiedenmann *et al.*, 1986; Weber, 1995), but is not entrained by LD cycles (Wiedenmann *et al.*, 1986). When animals were transferred to aperiodic conditions such as LL for a prolonged period prior to ecdysis, rhythmicity in cuticle deposition still commenced at ecdysis throughout the animal and was maintained daily thereafter (Wiedenmann *et al.*, 1986). It was inferred that the initiation of banding in the cuticle occurs at ecdysis by some unidentified signal. This signal could be a hemolymph factor, perhaps a hormone, released around the time of ecdysis (Lukat *et al.*, 1989). This unknown signal was apparently unnecessary for the maintenance of the rhythm after its initiation, since the banding rhythm continued in leg pieces that were implanted into older animals in which cuticle rhythmicity had ceased (Lukat *et al.*, 1989). In some species, this signal may occur prior to ecdysis because several daily bands may already be present in the cuticle immediately after ecdysis (Kristensen, 1966). Together, these studies of cuticular banding suggest that rhythmicity is initiated at or before ecdysis by a humoral agent, perhaps a hormone. The rhythm appears not to require additional inputs after ecdysis. These features sustain the possibility that rhythmicity is initiated by (rhythmic) hemolymph ecdysteroids at or prior to ecdysis. Once the rhythm is initiated, continuous input seems to be unnecessary; indeed the hemolymph ecdysteroid levels seen after ecdysis are very low (Steel and Vafopoulou, 1989).

A further consideration in understanding the regulation of rhythmic cuticle deposition involves *per*-based oscillators that may reside in, or close to, the epidermis. Rhythmic *per* expression was found in several peripheral tissues in *Drosophila*, including the thorax, legs, and wings (Plautz *et al.*, 1997). In this insect, the thoracic apodemes exhibit a daily rhythm in cuticle bands (Johnston and Ellison, 1982). It is therefore possible that *per*-based peripheral oscillators may drive the cuticular rhythm in

apodemes. However, the general body cuticle of *Drosophila* does not show daily growth bands. It seems important to determine whether *per* expression is seen specifically in epidermal cells and whether the peripheral oscillators noted in appendages are entrainable by humoral signals.

3.11.4.3. Circadian Regulation of Ecdysis

The endocrine regulation of ecdysis is treated elsewhere (see **Chapter 3.1**). Previous reviews include Reynolds (1980, 1987), Truman and Morton (1990), Truman *et al.* (1991), Hesterlee and Morton (1996), Horodyski (1996), Ewer *et al.* (1997), Nässel (2000), Predel and Eckert (2000), Jackson *et al.* (2001), Ewer and Reynolds (2002), and Mesce and Fahrbach (2002). This section addresses only those aspects of the subject that bear on the control of the timing of ecdysis.

The term ecdysis refers to the complex of behaviors by which an insect extracts itself from an old exoskeleton. Eclosion refers specifically to the adult ecdysis of holometabolous insects. Since every particular ecdysis occurs only once in the lifetime of an insect, circadian rhythms in ecdysis can be detected only in a population of insects of mixed ages. Such circadian "gating" of ecdysis has been described in numerous species of insects. The subject has long been of particular importance to circadian biology, the conceptual foundations of which were elucidated using the eclosion rhythm of *Drosophila* (see Pittendrigh, 1993). *Drosophila* continues to be the organism of choice for genetic manipulations of both eclosion and the molecular machinery of circadian clocks in general (Stanewsky, 2002, 2003; Hall, 2003) (see **Chapter 4.11**). By contrast, knowledge of the physiology and endocrinology of ecdysis derives almost exclusively from the large moths *A. pernyii*, *Hyalophora cecropia*, *M. sexta*, and *B. mori*.

Ecdysis occurs as soon as sufficient new cuticle is deposited below the old cuticle to provide sufficient structural support for both the insect as a whole and for its internal organs. A preecdysis sequence of behaviors then occurs, which serves to loosen remaining attachments between the new and old cuticles, followed by an ecdysis sequence characterized by rhythmic peristaltic contractions of the abdomen that propel the old cuticle away, revealing the new cuticle. The new cuticle is then inflated by swallowing air or water and then hardened by quinone tanning of cuticular proteins (see **Chapter 4.4**). At the time of ecdysis, the new cuticle is usually no more than half its final thickness. Cuticle secretion continues for days or weeks after ecdysis (as do many other components of the molting process, including muscle development and remodeling of neural circuits). Ecdysis is often, but incorrectly, described as the final event in molting or as occurring at the end of the molting process.

Insects seem to have experienced strong selective pressure to undergo ecdysis as early as possible during the molting process. The presence of two cuticles around the body, one of which is loose, encumbers locomotion and makes chewing difficult. Further, the presence of two cuticles within the tracheal system impairs gas exchange. Insects seek secluded locations away from predators once new cuticle formation is under way. These considerations illustrate that the time of ecdysis must be intimately coordinated with the progress of cuticle secretion. The latter is governed primarily by systematic changes in the titer of hemolymph ecdysteroids (Steel and Vafopoulou, 1989). Thus, the time of ecdysis is coordinated with molting via ecdysteroids. There is considerable experimental support for this view, summarized below. Coordination of ecdysis with molting does not necessarily involve circadian timing. The fact that circadian timing usually finetunes the relationship with the timing of molting is often ascribed to the need for ecdysis to take place at a time of day when predators are inactive.

There is an additional set of reasons why circadian control is needed in the case of the adult ecdysis. Closely related species may have eclosion gates that are separated by many hours. Many species mate soon after adult eclosion. Gating of eclosion may therefore serve to ensure that mating occurs between members of a single species and therefore may represent a mechanism for reproductive isolation. A secondary consequence of the timing of mating by the timing of eclosion is that the reproductive states of males and females become synchronized with each other; this in turns creates synchrony in the processes of reproduction within the population as a whole. The gating of eclosion has classically been ascribed to the action of a brain-centered "eclosion clock" (Truman and Riddiford, 1970; Truman, 1972b). Only two inputs have been documented that influence the timing of ecdysis: ecdysteroids and an eclosion clock. Whether or not the mechanisms that control ecdysis differ between larval and adult ecdyses has been debated extensively in the literature (Truman *et al.*, 1981; Ewer and Reynolds, 2002).

The importance of ecdysteroids in timing ecdysis was first shown by Slama (1980). He found that injection of 20E into pharate adult *Tenebrio molitor* delayed ecdysis. Using *Manduca*, Truman *et al.* (1983) reported that 20E injection appeared to affect both the pupal ecdysis and eclosion, but

in different ways (Figure 17a and b). When physiological doses of 20E (1 µg or less) were injected within 8 h of ecdysis, the delay in the time of ecdysis was progressive and dose dependent in both larvae and pupae. But at supraphysiological doses (5 µg or more) the pupal ecdysis was prevented whereas eclosion was not. The high doses of 20E induced discontinuous delays in eclosion, with the animals "jumping" to progressively later eclosion gates as the dose of 20E was increased (Figure 17b). This effect was attributed to a direct circadian control over eclosion (by the brain) that was presumed to be absent from larvae. This conclusion was consistent with earlier studies (Truman, 1972a) reporting that the ecdysis gate for larvae of *Manduca* became fixed at the HCP for decapitation (see Section 3.11.4.1.1) and that phase shifts of the light cycle applied after the HCP failed to generate phase shifts in the time of ecdysis. Since the HCP is a gated event, it was inferred that the gating of larval ecdyses was set by prior endocrine events that control molting. These events were presumed to involve the circadian control of PTTH release and, by association, ecdysteroid levels (Ewer and Reynolds, 2002) (see Section 3.11.4.1). Collectively, these experiments showed that ecdysis of all instars requires a decline in the

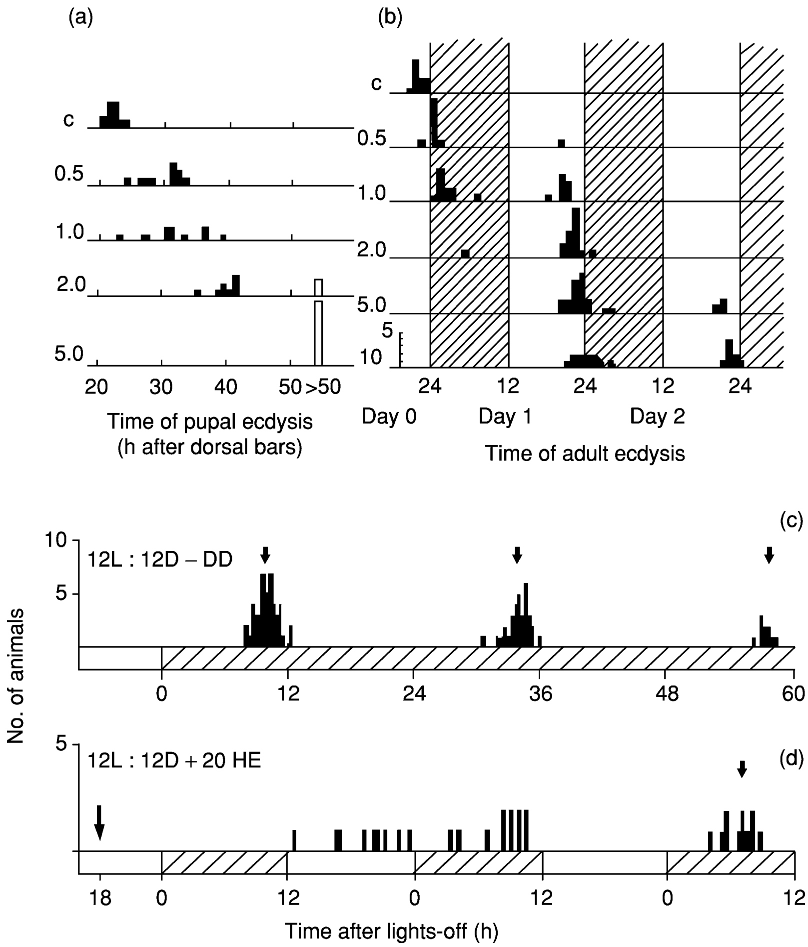

Figure 17 Upper panel: injection of increasing amounts of 20-hydroxyecdysone (20E) produces increasing delays of the time of (a) pupal ecdysis and (b) adult eclosion in *Manduca sexta*. The time of pupal ecdysis is delayed progressively as the dose of 20E increases. The same is true for eclosion for small doses of 20E; however, at higher doses of 20E the time of eclosion is displaced into the following gate. Open bars indicate animals that did not undergo ecdysis and (c) indicates the ecdysis time of control animals. Amounts of 20E injected range from 0.5 to 5.0 µg. (Reprinted with permission from Truman, J.W., Rountree, D.B., Reiss, S.E., Schwartz, L.M., **1983**. Ecdysteroids regulate the release and action of eclosion hormone in the tobacco hornworm, *Manduca sexta*. *J. Insect Physiol. 29*, 895–900; © Elsevier.) Lower panel: in *Rhodnius prolixus*, the imaginal ecdysis rhythm free-runs in DD (c). Injection of 40 ng 20E (8% of the lowest dose used in *Manduca*) at the long arrow in (d) abolishes the first gate after injection, but timing recovers in subsequent gates. The response resembles (a) rather than (b) in *Manduca*. (Reproduced with permission from Steel, C.G.H., Ampleford, E.J., **1984**. Circadian control of hemolymph ecdysteroid titres and the ecdysis rhythm in *Rhodnius prolixus*. In: Porter, R., Collins, G.M. (Eds.), Photoperiodic Regulation of Insect and Molluscan Hormones. Pitman Press, London, pp. 150–169; © John Wiley & sons Ltd.)

titer of ecdysteroids. Such a decline is characteristic of the period of exocuticle deposition during molting (Steel and Vafopoulou, 1989), and illustrates the role of ecdysteroids in coordinating the time of ecdysis with the progress of molting. Thus, a steadily declining ecdysteroid titer would provide the ecdysis control system with information about which of the daily ecdysis gates should be employed by an individual insect. This has been the preferred model for the eclosion of moths for many years; the silkmoths *Antheraea* and *H. cecropia* appear to have a circadian clock in the brain that is specific for the control of eclosion (Truman and Riddiford, 1970; Truman, 1972b) and the hemolymph ecdysteroid titer of *Manduca* contains no information about circadian time as it exhibits no clear circadian rhythmicity (Schwartz and Truman, 1983).

In a growing number of species, the hemolymph ecdysteroid titer shows circadian oscillations (see Section 3.11.4.1.3). In such species, the circadian time signals conveyed by the ecdysteroid titer could regulate the circadian gating of ecdysis without the involvement of a specific ecdysis clock. For example, ecdysis in the silkmoth *Bombyx* is tightly gated (Sakurai, 1983) and the ecdysteroid titer exhibits a daily rhythm (Sakurai *et al*., 1998; Mizoguchi *et al*., 2001). Interestingly, the time of ecdysis is set early in molting in both *Manduca* (Truman, 1972a) and *Bombyx* (Sakurai, 1983); in *Bombyx* the time is set on the day in which rhythmicity in ecdysteroids commences (Sakurai *et al*., 1998). It is possible that the precision with which ecdysteroid titers are timed in various species influences the precision with which ecdysis is gated.

All ecdyses in *Rhodnius* are tightly gated (**Figure 17c**) (Ampleford and Steel, 1982) and the circadian regulation of ecdysteroids has been extensively studied in this species (see Section 3.11.4.1.3). In *Rhodnius*, unlike *Bombyx*, the gate for ecdysis can be phase-shifted for many days after the onset of rhythmicity in the ecdysteroid titer (Ampleford and Steel, 1982, 1985), presumably because the rhythm in ecdysteroids is itself entrainable by light (see Section 3.11.4.1.3); it is not known if the same occurs in *Bombyx*. In *Rhodnius*, injection of a much smaller dose of 20E than was used with *Manduca* much longer in advance of ecdysis has a dramatic influence on the gating of ecdysis (**Figure 17d**). The first ecdysis gate is abolished and animals emerge outside the gate until the time of the second gate, when gating is restored. It seems that *Rhodnius* ecdysis is extremely sensitive to small perturbations of ecdysteroid levels (see discussion by Ewer and Reynolds, 2002). The intimate relation between the gating of ecdysis and the ecdysteroid titer rhythm was revealed in *Rhodnius* by experiments showing that manipulations of the ecdysteroid titer led to predictable changes in the ecdysis rhythm (Ampleford and Steel, 1986). Thus, circadian time signals present in the circulating ecdysteroid titer provide important signals that regulate the gating of ecdysis. Nevertheless, factors other than the ecdysteroid rhythm appeared to be involved in generating the rhythm of ecdysis (Ampleford and Steel, 1986).

From the above it is apparent that the ecdysis control system reads the circulating levels of ecdysteroids to determine the developmental readiness for ecdysis, i.e., which of the daily gates will be used by an individual insect. This information is contained in the ecdysteroid titer whether or not it is under circadian control. In those species where the ecdysteroid titer also contains circadian information, this information contributes to the timing of ecdysis within a day, i.e., to the gated nature of ecdysis. Indeed, it would be strange if such circadian input to the ecdysis control system was ignored.

How and where do ecdysteroids act on the system that controls ecdysis? No clear evidence exists in the literature, but some possibilities have been raised. The ecdysis control system consists of eclosion hormone (EH) synthesized in ventromedial (VM) neurons in the protocerebrum of the brain, ecdysis triggering hormone (ETH) and preecdysis triggering hormone (PETH) synthesized in Inka cells of segmentally repeated epitracheal glands and crustacean cardioactive peptide (CCAP) synthesized in segmentally repeated neurons in the abdominal ganglia (see **Chapter 3.1**). The nature and mechanism of interactions between these peptides and their roles in coordination of ecdysis are the subjects of continuing research with many regulatory schemes in the literature. Some recent schemes are given by Žitňan and Adams (2000), Jackson *et al*. (2001), and Ewer and Reynolds (2002) (see **Chapter 3.1**). EH was the first of these neuropeptides to be discovered and has the most extensive literature (see Truman, 1992). Early evidence indicated two links between ecdysteroids and EH. The decline in the ecdysteroid titer to some critical value is necessary for both the initiation of release of EH and for the acquisition of the ability of the CNS to respond to EH (Truman *et al*., 1983; Morton and Truman, 1988). EH synthesis is apparently not regulated by ecdysteroids, since EH mRNA is continuously present in the cells from the embryo to the adult (Riddiford *et al*., 1994). The VM neurons of adult *Drosophila* possess a branch that terminates in the vicinity of the lateral clock neurons (Siegmund and Korge, 2001), suggesting a site for clock input at eclosion. This branch is not seen in the larval stages

of *Manduca* (Truman and Copenhaver, 1989), consistent with earlier evidence of a brain clock controlling eclosion in *Manduca*. However, the VM neurons do not seem to be necessary for either larval ecdysis or for eclosion. An expression system was used to drive transcription of cell death genes in the VM neurons of *Drosophila* (McNabb *et al*., 1997; Baker *et al*., 1999). These “EH knockout” flies exhibited important defects in ecdysis behavior in most cases, but about one-third of the flies completed all ecdyses and emerged as adults. Moreover, these flies exhibited a normal circadian rhythm of eclosion (McNabb *et al*., 1997). These findings suggest that although EH may be a normal component of the ecdysis control system, in the absence of EH both ecdysis behavior and the mechanism that times the behavior can be activated by alternate pathways. Jackson *et al*. (2001) concluded that multiple pathways must be present by which timed ecdysis can be initiated.

Ecdysteroids affect the Inka cells directly and in several ways. The rising ecdysteroid titers early in the molt induces EcR and then expression of the *eth* gene, leading to synthesis of both ETH and PETH in the Inka cells. The *eth* gene contains ecdysone response elements (Žitňan *et al*., 1999). By contrast with EH (above), deletion of the *eth* gene prevented ecdysis in 98% of animals and death occurred at the transition from first to second instar (Park *et al*., 2002). Ecdysteroids also suppress the development of responsiveness of the Inka cells to EH (Kingan and Adams, 2000) and are necessary for the abdominal nervous system to develop sensitivity to ETH. EH and ETH each promote the release of the other (Ewer *et al*., 1997; Kingan *et al*., 1997); thus, timed ecdysteroid signals to either the VM cells or the Inka cells would result in timed release of both EH and ETH. Both peptides activate the CCAP neurons in the abdominal ganglia; local release of CCAP acts as a proximate trigger of the ecdysis motor program (Gammie and Truman, 1997). The relative importance of EH (Ewer *et al*., 1997; Gammie and Truman, 1997) and ETH (Žitňan and Adams, 2000) in activating the CCAP pathway is currently debated. The CCAP neurons themselves may be additional targets of ecdysteroid action (Žitňan and Adams, 2000; Jackson *et al*., 2001) (see **Chapter 2.4**).

In summary, ecdysteroids appear to influence all the neuropeptides comprising the ecdysis control system, creating numerous potential control points for the timing of ecdysis by ecdysteroids. Operating in concert, these controls would effectively confine ecdysis behavior to a very narrow time window, even without input from a brain clock. Such may be the case in those larval ecdyses that are rather loosely gated. If the ecdysteroid titer is itself under circadian control, this circadian timing could readily drive the ecdysis control system and result in circadian gating of ecdysis. The additional “direct” circadian timing of eclosion by the brain in some species may result from the differentiation during development of contacts between the VM neurons and the clock neurons in the brain. This additional source of timing information might increase the precision of timing with which EH is released, with consequent tighter synchrony between the release of EH and PETH/ETH and also enhanced synchrony among the segmentally repeated Inka cells. The advent of a brain-centered timing mechanism at eclosion could be associated with a deterioration in ecdysteroid-based timing associated with degeneration of the prothoracic glands at the end of larval life. As noted earlier in this section, precision of timing is especially critical at the adult ecdysis; therefore, direct circadian timing of EH release might represent a compensation for deterioration of ecdysteroid-based timing at this critical time.

3.11.4.4. Circadian Regulation of Egg Hatching

Egg hatching refers to the behaviors by which the first larval instar liberates itself from the confines of the egg shell, employing muscular contractions of the body and/or gnawing or chewing movements using cuticular structures known as egg bursters. Egg hatching is therefore the first manifestation in the life cycle of an insect of its ability to express complex behavioral patterns. Hatching occurs only once in the life of an insect; it is inextricably coordinated with the timed events of embryonic development. In an insect population entrained to stable LD cycles, egg hatching occurs with regularity and consistency at restricted times of the day; it is therefore a gated phenomenon. The time of hatching is not determined by the time of oviposition. Numerous studies have shown that the hatching rhythm is circadian in nature; it free-runs under continuous light conditions and is entrainable by light and/or temperature cycles (see below). Early experiments by Minis and Pittendrigh (1968), for example, showed that eggs of *Pectinophora gossypiella* raised in LD exhibited a distinct daily rhythm of hatching, whereas eggs raised in aperiodic conditions (LL) showed arrhythmic hatching. The rhythm could be initiated by transfer of eggs from LL to DD. Similarly, daily rhythms of egg hatching have been described in various Lepidoptera and Orthoptera; for example, the hatching rhythms of the southwestern corn borer *Diatraea grandiosella* (Takeda, 1983), the silkmoth *Antheraea* (Sauman *et al*.,

1996), and the house cricket *Gryllus* (Tomioka *et al*., 1991) all free-run in DD. Collectively, these studies show that egg hatching is controlled by an endogenous circadian oscillator, which differentiates and becomes functional prior to hatching. Thus investigations concerning egg hatching have focused on how hatching is coordinated with the progression of embryogenesis and when during embryonic development the clock that controls hatching becomes detectable.

Minis and Pittendrigh (1968) transferred arrhythmic eggs from LL to DD at various times throughout embryonic development. They obtained rhythmic hatching only from eggs transferred to DD at 50–60% of development or later; transfers at earlier times failed to induce rhythmicity in hatching. In a converse experimental design, when eggs of *Gryllus* were transferred to LL at 60% of embryogenesis or later, hatching remained rhythmic. But if transfer to LL occurred prior to 60% of embryonic development, then the larvae hatched arrhythmically (Tomioka *et al*., 1991). Similar findings were reported by Sauman *et al*. (1996) for *Antheraea*. Interestingly, Itoh and Sumi (2000) suggested that the egg hatching rhythm of *Gryllus* was not strictly dependent on entrainment of the embryos to a light regime but appeared to be influenced by the mother as well; this implies the involvement of a maternal factor in the development of the circadian time keeping system in the embryo (possibly melatonin) (**Figure 19**). Together, these findings show that an endogenous photosensitive circadian clock that controls egg hatching becomes functional at about 50–60% of development. This suggests that some component of the timekeeping system, such as the light entrainment pathway or the clock itself, is either not differentiated or not fully functional prior to this point in embryonic development. Minis and Pittendrigh (1968) found that entrainment of hatching to temperature cycles became possible at about the same time as light entrainment became possible, indicating that both clock and entrainment pathways become functional at about the same time of embryogenesis. Further, exposure of eggs of *Pectinophora* to various wavelengths of monochromatic light during the second half of embryonic development demonstrated that the embryos were most sensitive to monochromatic light of 390–480 nm. This range of light sensitivity suggested that carotenoid-based photoreceptors could be responsible for light entrainment in these embryos. By contrast, carotenoid-depleted eggs of *Bombyx* (raised on a carotenoid-deprived diet) showed normal patterns of egg hatching rhythmicity, even though the resulting first instar larvae exhibited massively reduced ocellar photosensitivity and suppressed phototaxis (Sakamoto and Shimizu, 1994). It is therefore possible that the light input pathway for the hatching rhythm may be different from that of other major rhythms such as the locomotion rhythm. In conclusion, the above observations show that both clock and entrainment pathways become established and functional at 50–60% of embryogenesis.

What developmental events occur in the embryo at this time and are they implicated in the physiological control of hatching? Neurogenesis begins at about 20–25% of embryonic development in *Drosophila* (Doe and Goodman, 1985), *Manduca* (Dorn *et al*., 1987a), and grasshoppers (Jan and Jan, 1982). By 30% of development differentiated neurons, glial cells and sheath cells appear (Thompson and Siegler, 1993). In the CNS of *L. migratoria*, synapses and action potentials become detectable at about 70% of development (Leitch *et al*., 1992). Nerve cells that are essential to both development and circadian time keeping become differentiated and functional during embryogenesis. Neurosecretory cells of *Manduca* become immunopositive for PTTH around 24–30% of development (Westbrook and Bollenbacher, 1990). At this young age, PTTH biological activity can also be extracted from embryos (Dorn *et al*., 1987b). By 80% of development, the basic neuroarchitecture of these cells has been established, including axons that terminate in the CA (Westbrook and Bollenbacher, 1990). PTTH material active in bioassays was also extracted from *Bombyx* embryos in the second half of embryogenesis (Chen *et al*., 1987). In *Locusta*, immunoreactivity for PTTH was detected in late embryos (Goltzene *et al*., 1992). Differentiation of PGs begins around 40% of development in *Manduca* (Dorn *et al*., 1987a) and *Locusta* (Lagueux *et al*., 1979). Whether or not these young PGs are engaged in the synthesis of ecdysteroids is unclear (see below). Eggs are deposited with a rich supply of maternal ecdysteroids, mainly in the form of inactive conjugates. It is generally accepted that ecdysteroids are essential for the embryonic molts (Hoffmann and Lagueux, 1985; Kadono-Okuda *et al*., 1994). Embryos undergo one or more embryonic molts, the number varying with the insect species. For example, embryos of *L. migratoria* deposit three embryonic cuticles prior to hatching; the first, the serosal cuticle, appears at 20% of development. It is followed by the first embryonic molt at about 35% and then by the second embryonic molt at about 45% of development. At 75–80% of development the cuticle of the first larval instar is deposited. Peaks of ecdysteroids precede each embryonic molt

(Hoffmann and Lagueux, 1985). *Manduca* undergoes two embryonic molts (Dow *et al*., 1988). However, Diptera (including *Drosophila)* do not form embryonic cuticles prior to that of the first instar larva at about 75–80% of development. Embryonic molts closely correlate with increases in biologically active ecdysteroid (Dorn, 1983; Lanzrein *et al*., 1985; Slinger and Isaac, 1988). Whether active ecdysteroids are synthesized *de novo* in the embryos (Beydon *et al*., 1989; Dorn, 1983; Slinger and Isaac, 1988; Espig *et al*., 1989; Horike and Sonobe, 1999; Warren *et al*., 2002) or are produced by conversion of the inactive stored deposits (Sall *et al*., 1983; Bownes *et al*., 1988; Thompson *et al*., 1988; Kadono-Okuda *et al*., 1994) seems to vary among species. In *Bombyx,* Kadono-Okuda *et al.* (1994) applied an inhibitor of ecdysone synthesis to females at various stages of vitellogenesis, resulting in eggs with various amounts of stored ecdysteroids. The authors found that these eggs containing different amounts of ecdysteroids completed different degrees of embryonic development, and they concluded that ecdysteroids provided by the mother were essential for the normal progress of embryogenesis and egg hatching. Regardless of the origin of active ecdysteroids, the embryo apparently possesses the ability to count time and to determine when active ecdysteroids are needed for molting.

Several other neurohormones potentially important for the insect timekeeping system are also present in embryos. Truman *et al.* (1981) found that *Hyalophora* embryos contained material that was active in eclosion hormone bioassays. The amount of this material dropped at the times of embryonic ecdyses, but not at hatching. However, Fugo *et al.* (1985), obtained converse results in *Bombyx*: eclosion hormone activity did not fluctuate during embryonic molts but dropped abruptly following hatching. JH was also detected in embryos of several insects such as the cockroach *Nauphoeta cinerea* (Lanzrein *et al*., 1985), the locust *Locusta* (Temin *et al*., 1986), and *Bombyx* (Gharib and DeReggi, 1983) (review: Truman and Riddiford, 2002).

Where is the clock that controls egg hatching located in the embryo? The first detection of photic entrainment of the egg hatching rhythm in *A. pernyi* (50–60% of development) coincides with the first appearance of PER and TIM clock proteins in four pairs of cells of the embryonic brain (Sauman *et al*., 1996). Staining in the brain was exclusively cytoplasmic and did not exhibit daily oscillations in and out of the nuclei, as is required of cells possessing a molecular oscillator (see **Chapter 4.11**). At 60–70% of development, PER and TIM immunoreactivity was detected in the nuclei of midgut epithelial cells. In this location, staining exhibited robust daily oscillations that free-ran in DD. Treatment of embryos the day before hatching with *per* antisense oligodeoxynucleotide not only decreased PER immunoreactivity dramatically, but also abolished the egg hatching rhythm. Control embryos injected with a reverse orientation antisense oligonucleotide of *per* retained rhythmicity. Therefore, the *per* gene products are essential for the expression of egg hatching rhythm. Sauman and Reppert (1998) then examined the roles of brain and midgut in the control of the egg hatching rhythm (**Figure 18**). Brains from embryos 1 day before hatching were transplanted into recipient embryos, which were entrained to a light cycle that was phase delayed by 8 h relative to the donor brains. Hatching was then monitored in DD. It was observed that the implanted brain dictated the phase of hatching (**Figure 18**). By contrast, transplants of midgut did not affect the time of hatching. It became clear from these experiments that the brain is responsible for the regulation of the timing of hatching within a day (i.e., the hatching gate). This regulation is apparently achieved by the release of a "chronoactive" humoral factor from the brain, possibly a neurohormone. It was inferred that the PER-positive cells in the brain constitute the clock responsible for the egg hatching rhythm despite the failure of PER to oscillate in these cells. These cells appear to correspond to the PER-positive cells found in the brain of adult *Antheraea* (Sauman and Reppert, 1996a), which appear to regulate the release of PTTH (see Section 3.11.4.1.2). The brain also regulates the circadian cycling of PER into the nuclei of midgut epithelial cells, but this regulation requires intact nervous connection of the midgut with the brain and does not depend on a diffusible chronoactive substance from the brain. The role of this midgut oscillator is unknown. It is possible that it regulates the timing of deconjugation of maternal ecdysteroids during embryonic molts. These considerations suggest another possible pathway by which the brain might regulate ecdysteroids during embryonic molts.

Melatonin is a well-established mediator of photoperiodic information in vertebrates and a crucial element of their timekeeping system. Embryos of *Gryllus* contain both melatonin (**Figure 19b**) and *N*-acetyltransferase (NAT) (**Figure 19a**), a key enzyme in the synthetic pathway of melatonin (Itoh and Sumi, 1998a, 1998b). Freshly laid eggs contain a rich supply of melatonin of maternal origin (**Figure 19b**) (Itoh *et al*., 1994, 1995a, 1995b). At about 20% of embryonic development, the level of melatonin in the eggs begins to show a clear daily

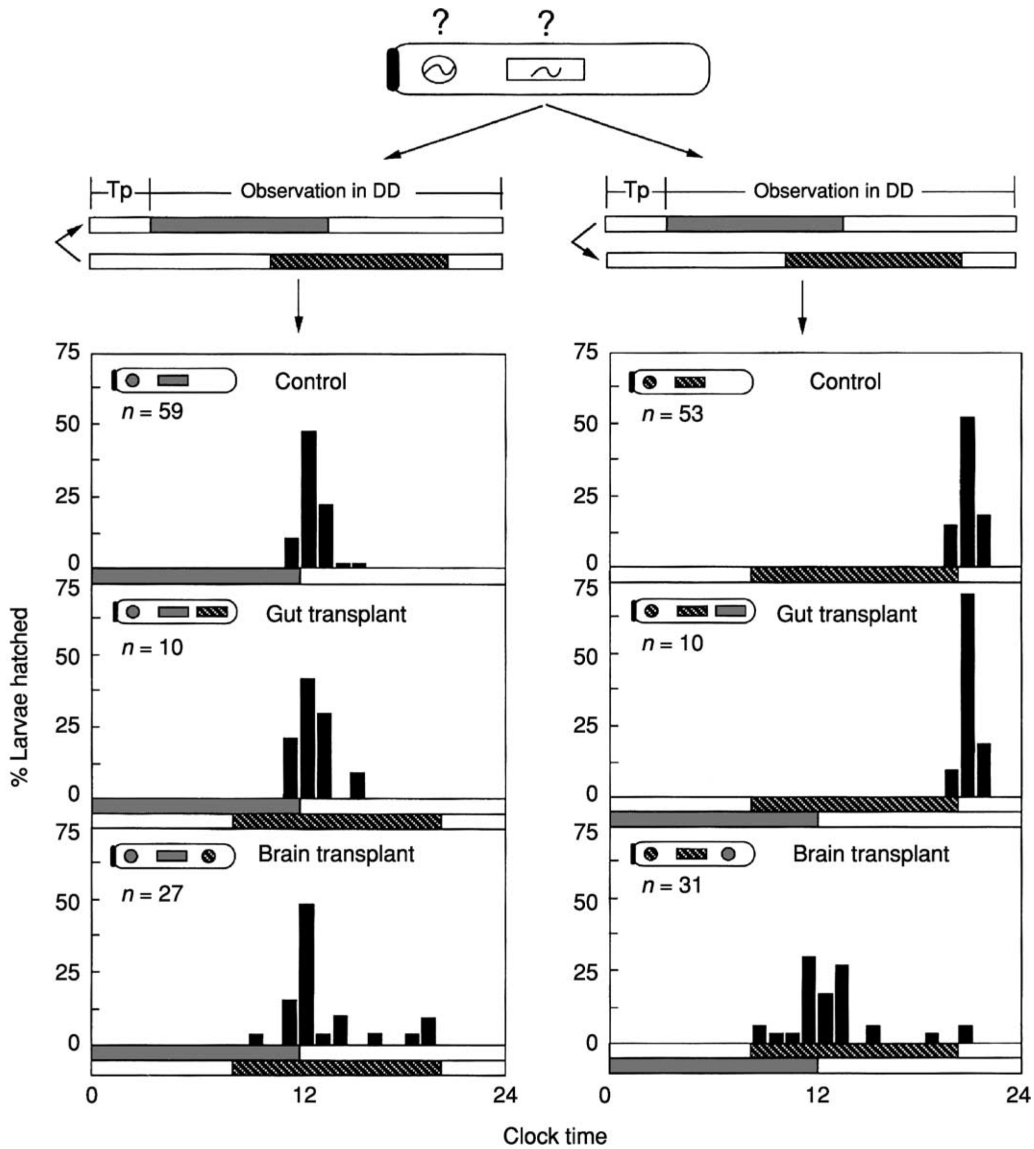

Figure 18 Experiments demonstrating a diffusible factor from the brain of developing first instar larvae of the silkmoth *Antheraea pernyi* that controls the circadian gating of egg hatching behavior. Brains or midguts of embryos were transplanted (Tp) into host embryos 1 day before egg hatching. Host embryos were entrained to a light cycle that was 8 h delayed (panels on left) or 8 h advanced (panels on right) relative to the light cycle of donor embryos. The embryos were transferred to DD following surgery and allowed to hatch. The experiments on the left show that when donor guts (middle panel) or donor brains (bottom panel) were obtained from embryos that were 8 h phase delayed relative to the host, the time of hatching of host embryos occurred at the same time as that of controls (top panel). This shows that the circadian gate of hatching is determined by the host and the subsequent release of any factors from implanted tissues is redundant. Right panels show equivalent experiments using implants that were 8 h phase advanced relative to the host. Implantation of midgut did not affect the hatching time (middle panel; compare with control panel above). However, implantation of brain advanced the time of hatching to 8 h earlier than it would normally occur in controls (bottom panel). This shows that the implanted brain releases a factor that times hatching. This factor can be detected when it is released earlier than that of the intrinsic brain but not when it is released later. rhythm; this time coincides with the first appearance of NAT in the eggs (Itoh and Sumi, 1998a, 1998b). By 40% of development, NAT was shown to free-run in DD, suggesting that clock control of NAT was operative at this time. The rhythm was also light entrainable. These experiments show that circadian control of NAT and possibly of melatonin synthesis are initiated around mid-embryogenesis in crickets. The significance of melatonin in timekeeping in vertebrates suggests that work with melatonin in insects merits further investigation.

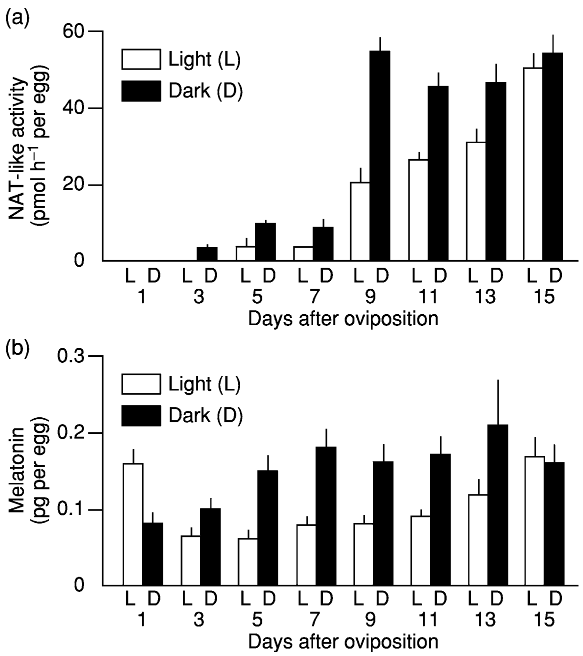

Figure 19 Changes in *N*-acetyltransferase (NAT)-like activity (a) and melatonin (b) between photophase (L) and scotophase (D) during embryogenesis of the cricket *Gryllus bimaculatus*. First instar larvae hatch around days 16–18. Newly laid eggs are devoid of NAT activity; activity is first detected at day 3 and from then on it shows daily periodic changes until hatching with highs in scotophase and lows in photophase. In contrast, melatonin is present in newly oviposited eggs. After day 3, the level of melatonin changes rhythmically with highs during scotophase and lows during photophase, suggesting intrinsic synthesis by the embryo. Photosensitivity and ability for timekeeping in the embryos of *Gryllus* is apparently established around the middle of embryogenesis. (Reprinted with permission from Itoh, M.T., Sumi, Y. **1998a**. 3.11.5. The Adult Endocrine System

3.11.5.1. Circadian Regulation of the Adult Endocrine System

All the major developmental hormones (PTTH, ecdysteroids, and JH) persist in the adult. Their roles in circadian timekeeping may also persist into the adult. Rhythms in hemolymph JH levels have been reported and pathways of clock control over the CA are known. By constrast, PTTH and ecdysteroid titers have not yet been shown to be rhythmic in adults, even though there are extensive data on these rhythms in larvae. Ecdysteroids and JH have long been known to play key roles in the regulation of reproduction. There are numerous circadian rhythms in endocrine and behavioral events that are organized around and within reproductive cycles, which raises the prospect that these hormones may also be involved in the circadian organization of reproduction.

PTTH, whose role in the circadian organization of larvae was discussed above (see Section 3.11.4.1.2), is also found in various adult insects. The first purification of PTTH employed heads of adult *Bombyx* (Ishizaki and Suzuki, 1994); PTTH was later identified at high levels in adult hemolymph (Mizoguchi *et al.*, 2001). Likewise, the brain of adult *Rhodnius* both contains and releases high quantities of biologically active PTTH (Vafopoulou *et al.*, 1996); further, the PTTH cells in the larval brain and their associated clock neurons persist in the adult brain (Terry and Steel, 2004). Similarly, the PTTH cells and the clock neurons that regulate PTTH release are also present in the brain of adult *Antheraea* (Sauman and Reppert, 1996b). There is therefore considerable evidence that the machinery for circadian regulation of PTTH persists in the adult. Even though the function of PTTH in the adult is currently unknown (see **Chapter 3.2**), it is conceivable that PTTH is as important to the circadian organization of the adult as it is in larvae. It is tempting to speculate that PTTH of adults continues to function in the regulation of ecdysteroids.

Ecdysteroids are present in the adult, where they are involved in various aspects of egg and sperm production and, along with JH, could be considered as the gonadotropins of insects (De Loof *et al.*, 2001). The primary source of ecdysteroids in larvae, the PGs, degenerate soon after ecdysis to the adult, but production of ecdysteroids continues in the adult by other tissues, such as the ovaries and testes. The hemolymph levels of ecdysteroids are much lower in adults than in larvae and consequently rhythmicity in ecdysteriod levels in adult insects has not yet been detected.

Synthesis and release of JH by the CA continues in the adult stage (see **Chapters 3.7** and **3.9**) and there is recent evidence suggesting that it may play an important role in the circadian organization of the adult. In some instances, JH synthesis is under the control of clock cells in the brain, the hemolymph level of JH is rhythmic, and JH is intimately involved in the expression of many circadian rhythms in the adult. Some of this evidence is discussed below.

JH synthesis by the CA is regulated by nerves from the brain and involves stimulatory (allatotropin) and inhibitory (allatostatin) neuropeptide inputs (see **Chapter 3.7**). The pattern of distribution of allatotropin/allatostatin immunopositive neurons in the lateral region of the protocerebrum that project to the retrocerebral complex is quite similar among different groups of insects. In *Manduca*, for

example, lateral allatostatin neurons are organized into two groups; one neuron group, the Ib cells, project immunopositive ipsilateral axons directly to the CA (Žitňan *et al.*, 1995b). Similar situations of lateral allatostatin-positive neurons that arborize terminally in the CA were found in cockroaches (Stay *et al.*, 1994), crickets (Stay *et al.*, 1994), locusts (Veelaert *et al.*, 1995), several other lepidopterans (Jeon and Lee, 1999; Audsley *et al.*, 2000), and in the ring gland of *Drosophila* (Žitňan *et al.*, 1992). Allatotropin-immunopositive lateral neurons in the brains of both *Manduca* (Žitňan *et al.*, 1995a) and *Bombyx* (Park *et al.*, 2001) also possess axons that terminate in the CA. Thus, the regulation of JH synthesis by these compounds could occur locally in the CA. In addition, these peptides may be released into the hemolymph where they may exert other regulatory functions. There is neuroanatomical evidence of connections of the circadian system to the CA by direct connection with clock cells in the brain or by indirect connection of these clock cells with the allatotropin/allatostatin cells in the brain. In adults of *Antheraea*, four PER-immunopositive cells were localized in each brain hemisphere in the protocerebrum that form a neural network; the axons of these cells coalesce to form one neural tract that projects to the CA (Sauman and Reppert, 1996a). Therefore, there is a neural pathway in *Antheraea* between clock cells and the CA that could provide circadian input directly into the CA. The situation in *Drosophila* is slightly different. In *Drosophila*, two groups of neurosecretory neurons in the protocerebrum terminate at synaptic endings within the CA (**Figure 3**); both these groups of neurons have dendritic fields that synapse with, and presumably receive input from, the lateral clock neurons that are PDF-positive and show cycling of *per* and *tim* (Siegmund and Korge, 2001). Thus, clock neurons are connected to the CA in both *Antheraea* and *Drosophila*, potentially providing circadian input to the gland.

In contrast to the above evidence of allatotropins as targets of clock control, there is evidence that allatotropins may provide an input to the clock. In *L. maderae*, allatotropin-immunoreactive neurons are present in the accessory medulla (Petri *et al.*, 1995), adjacent to the optic lobe clock (see Section 3.11.3.1). Injections of allatotropin in the vicinity of the accessory medulla resulted in stable phase shifts in the rhythm of locomotor activity (Petri *et al.*, 2002). The phase-response curves produced by injection of allatotropin were closely similar to those produced by light pulses (**Figure 20**). In other words, pulses of allatotropin have a similar action on the clock as do pulses of light. The authors suggested that allatotropin-like compounds are either a functional unit of the clock itself or modulators of photic input to the optic lobe clock in cockroaches.

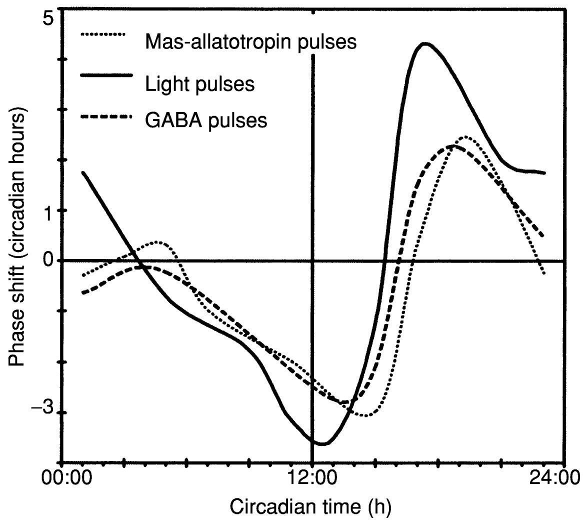

Figure 20 Phase-response curves of locomotor activity of the cockroach *Leucophaea maderae* obtained in response to injections of *Manduca* allatotropin (Mas-allatotropin), γ-aminobutyric acid (GABA), and 6 h light pulses. The close similarities of all phase-response curves suggests that both compounds may be released in response to light. (Reproduced with permission from Petri, B., Homberg, U., Loesel, R., Stengl, M., **2002**. Evidence for the role of GABA and Mas-allatotropin in photic entrainment of the circadian clock of the cockroach *Leucophaea maderae*. *J. Exp. Biol. 205*, 1459–1469; © The company of Biologists Ltd.)

Another mechanism that may be involved in the regulation of rhythmicity in the circulating levels of JH is clock-controlled availability of JH-binding proteins (JHBP) in the hemolymph (see **Chapter 3.7**). In *Drosophila*, the transcripts of the clock-controlled gene *take-out* (*to*) undergo daily cycling and free-run in DD; the circadian rhythm of *to* transcription is regulated by the *clock* and *cycle* clock genes (So *et al.*, 2000). Phylogenetic analysis of TO classifies it as a member of an insect protein superfamily that includes JHBPs from the hemolymph of *Manduca* and *Heliothis virescens*, a nuclear JHBP from epidermal cells of *Manduca* (Touhara and Prestwich, 1992; Touhara *et al.*, 1993; Wojtasek and Prestwich, 1995) and a putative protein from the head epidermis of *Manduca* that may be involved in JH binding (Du *et al.*, 2003). TO is more closely related to the hemolymph JHBPs than to the nuclear JHBPs. These observations suggest that the genes for JHBPs might also be clock-controlled. Though it is not known at present if TO binds the same ligands (if any) as JHBPs, these findings raise the exciting possibility that JH transport

and/or cell action may be regulated by the circadian availability of JHBPs.

Further indication of circadian regulation of JH comes from its involvement in rhythms of sensory responsiveness. JH plays an important role in the central nervous processing of sex pheromone olfactory input in males of *Agrotis ipsilon* (see **Chapter 3.15**). Males of this moth exhibit a daily rhythmicity of responsiveness to female sex pheromone that is synchronous with the daily rhythms of calling and pheromone release by females (Gemeno and Haynes, 2000) (see Section 3.11.5.4.1). Olfactory information is detected by antennal receptor neurons and then integrated centrally by interneurons in the antennal lobe (AL) of the brain (Anton and Gadenne, 1999; Gadenne *et al.*, 2001; Greiner *et al.*, 2002). Allatectomy of young males abolished behavioral responsiveness to sex pheromone (Gadenne *et al.*, 1993; Duportets *et al.*, 1996), even though the antennal olfactory neurons remained sensitive to pheromone signal (Gadenne *et al.*, 1993). Intracellular recording from the AL interneurons revealed that allatectomy significantly reduced their sensitivity to pheromone; moreover, injection of JH restored their sensitivity (Anton and Gadenne, 1999; Gadenne and Anton, 2000). Further, the proportion of AL interneurons that show sensitivity to pheromone stimulation was significantly lower in allatectomized males, but could be restored to normal levels with JH injections (Gadenne and Anton, 2000). The sensitivity to pheromones of antennal lobe interneurons increased with age and JH, whereas their sensitivity to plant volatiles was unaffected (Greiner *et al.*, 2002). Therefore, it appears that JH acts specifically on the central neural processing of sex pheromone input in males of *Agrotis*. Gadenne *et al.* (2001) showed that *Agrotis* males mate once every scotophase. Newly mated males exhibited a marked reduction in sensitivity in the antennal lobe neurons when exposed to female sex pheromones, whereas the peripheral olfactory neurons in the antennae remained highly sensitive. Sensitivity of the antennal lobe neurons recovered by the next scotophase, when the males were able to mate again. These findings show that the central neural processing system for sex pheromones undergoes daily fluctuations in sensitivity. Since this sensitivity is JH dependent, the possibility is raised that a daily rhythm of JH levels might underlie these rhythms of sensitivity.

Another example demonstrating that JH mediates rhythmicity in sensory interneurons is reported in the house cricket, *Acheta domesticus*. The males of *Acheta* exhibit a circadian rhythm of stridulation (Rence *et al.*, 1988) (see Section 3.11.5.4.2). Females recognize and respond to this acoustic sexual signal by exhibiting positive phonotactic behavior. Phonotactic behavior in females is regulated primarily by JH (Koudele *et al.*, 1987; Atkins and Stout, 1994; Stout *et al.*, 1998) (see **Chapter 3.15**). Allatectomy of females exhibiting phonotaxis resulted in decline in the directionality of behavior and sexual responsiveness, whereas topical JH application (Koudele *et al.*, 1987; Atkins and Stout, 1994) or CA transplantations (Stout *et al.*, 1976) restored them. It was found that phonotactic thresholds were regulated by changes in the level of JH, apparently by JH influencing the thresholds for firing action potentials in the L1 auditory interneuron; the L1 interneuron is a prothoracic ascending neuron that is essential for phonotactic responses to low-intensity calling songs. Intracellular and extracellular recordings of the firing of action potentials of the L1 interneuron revealed that allatectomy increased the phonotactic thresholds (Stout *et al.*, 1998). Topical application of JH onto the prothoracic ganglion or JH injection directly into the ganglion reduced both the firing thresholds of the L1 interneurons to nearly normal levels and the loudness of a mock calling song required to elicit phonotaxis (Stout *et al.*, 1998). The effects of applied JH were rapid and seen within 2 h. JH applications to other ganglia were ineffective (Stout *et al.*, 1991). Moreover, a daily rhythm in the threshold levels for phonotaxis was detected in day 3 females (Stout *et al.*, 1998), suggesting that a daily rhythm in JH levels may be the underlying cause for the observed changes in thresholds.

Evidence of daily rhythms in JH titers in hemolymph is accumulating. A clear daily rhythm is seen in *Gryllus firmus* (Zhao and Zera, 2004) (**Figure 21**), and day–night differences in JH titers are seen in *Apis mellifera* (Elekonich *et al.*, 2001) and *H. virescens* (Shu *et al.*, 1998). In the case of *Gryllus*, a clear JH rhythm is seen in the flight-capable (long-winged) morph, but only a weak rhythm is seen in the flightless (short-winged) morph; this finding again indicates a relationship between JH rhythmicity and behavior. In the case of honeybees, the transition from behavioral arrhythmicity of nursing bees to the rhythmic behavior of foraging bees was tentatively linked to the expression of the clock gene *per* in the brain (Toma *et al.*, 2000) (see **Chapter 3.13**). *per* expression in foragers cycles in a circadian fashion and free-runs in DD. Cycling of *per* is evident in both nurses and foragers. However, the relative levels of *per* mRNA and the amplitude of cycling increased significantly with the transition from nursing to foraging, consistent with the

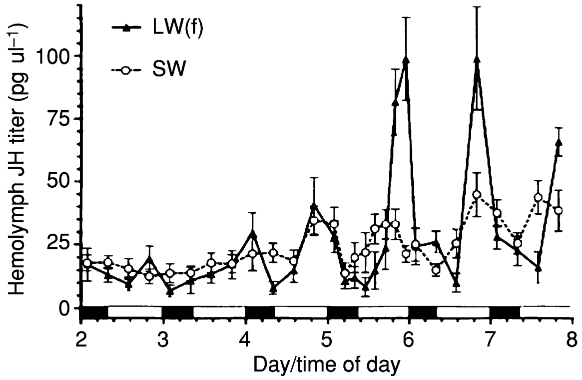

Figure 21 Daily rhythm in the hemolymph JH titer of the flight-capable (LW, long-winged) female morphs of *Gryllus firmus* (solid line). Note the daily peaks during day to night transitions. Flightless, short-winged (SW) females (dashed line) show only a weak daily rhythm in JH titer. (Reproduced with permission from Zhao, Z., Zera, A.J., **2004**. The hemolymph JH titer exhibits a large-amplitude, morph-dependent, diurnal cycle in the wing-polymorphic cricket, *Gryllus firmus*. *J. Insect Physiol. 50*, 93–102.)

pathways discussed above for control of JH by clock cells in the brain. In the honeybee *Apis cerana japonica*, *per* transcripts also oscillate daily in the brains of foragers; no comparisons were made with *per* transcrips in the brains of nurses (Shimizu *et al.*, 2001). These findings show that rhythmicity in JH titer does occur and that it may be driven by the brain.

A relationship between JH and behavioral activity rhythms is also seen in *Blattella germanica*. Males of this cockroach exhibit a bimodal circadian rhythm of locomotor activity that persists throughout their life cycle (Leppla *et al.*, 1989). Alternatively, females show a more complex pattern of locomotor activity that is clearly synchronized with the timing of each gonadotropic cycle. Immediately after emergence, the females exhibit a daily rhythm of locomotor activity. However, when they become sexually receptive during the first gonadotropic cycle, rhythmicity in locomotion is lost and the females become active throughout the day (Lee and Wu, 1994). Relative inactivity follows the expulsion of the first ootheca and then the females again become rhythmic for several days until the second gonadotropic cycle begins. Thus, rhythmic locomotion is confined to periods of expected high JH titer synchronized with gonadotropic cycles. Ovariectomy of sexually receptive females resulted in a stable circadian rhythm of locomotor activity, which was disrupted and reduced in amplitude by allatectomy (Lin and Lee, 1998). Therefore, factors associated with reproduction (perhaps ovarian factors) seem to mask the underlying circadian rhythm of locomotor activity. Topical application of JH increased the overall level of locomotor activity but it did not restore the behavioral circadian rhythm. However, JH applied topically enters the hemolymph continuously and over many days; this method of application does not provide a rhythmic supply of JH. Therefore, it is necessary to determine if JH synthesis is rhythmic in the cockroach in order to define its role in behavioral rhythms.

JH also appears to play a role in the regulation of rhythmic pheromone production in moths (see Section 3.11.5.3.1). In the females of the moth *A. ipsilon*, the pheromone level in the gland (Gemeno and Haynes, 2000), pheromone production by the gland (Picimbon *et al.*, 1997), and calling behavior (Gemeno and Haynes, 2000) all exhibit synchronous daily rhythmicities. Allatectomy of newly emerged females inhibited calling behavior; operated females neither contained nor released pheromone, even though their brain–SEG complexes contained high levels of activity of pheromone biosynthesis activating neuropeptide (PBAN) (Picimbon *et al.*, 1995). Apparently, the inhibitory effect of allatectomy on pheromone production was not solely due to disruptive effects on the gonadotropic cycle. Injections of PBAN or JH restored pheromone production but not rhythmicity in allatectomized females, suggesting that allatectomy prevented PBAN release. In contrast, JH III injections into decapitated females lacking a brain–SEG complex were ineffective in inducing pheromone production, suggesting that JH did not act directly upon the pheromone gland. Rather, JH appears to be necessary for the release of PBAN and it may do so by promoting release at “precisely gated times” (Picimbon *et al.*, 1995). Similarly, in *Helicoverpa armigera*, both pheromone production and PBAN levels are rhythmic (Rafaeli *et al.*, 1991). In this moth, JH treatment induced precocious pheromone production in newly emerged females (Fan *et al.*, 1999). However, if the animals were decapitated immediately after emergence, injections of neither JH nor PBAN were effective, whereas simultaneous injection with both compounds was stimulatory. Likewise, *in vitro* treatment with both JH and PBAN, but not either alone, induced pheromone production in inactive pheromone glands from pharate adults. These findings were interpreted as evidence that the role of JH is to prime the PBAN system. The possibility should be acknowledged that JH may play a permissive role in the above systems, i.e., its presence is required to allow these rhythmic phenomena to occur as opposed to actually controlling these rhythmicities. Elucidation of the role of JH in the regulation of daily pheromone release requires experiments on animals that

have commenced pheromone release and calling behavior.

Some general conclusions can be drawn from all the above. First, it appears that JH rhythmicity may be a widespread phenomenon among adult insects. Second, rhythmicity in JH could be responsible for the coordination of numerous circadian rhythms related to reproduction. Third, PTTH and ecdysteroids, which are known to be controlled by a circadian system in larvae, as well as the neuronal pathways that mediate their circadian control, all persist in the adult. Therefore, it is conceivable that circadian regulation of all three hormones, PTTH, ecdysteroids, and JH, participate in the regulation of rhythmic reproductive processes. Therefore, the putative central timing system in larvae that was discussed in the previous sections, may well continue functioning in the adult through circadian control of the same hormones. Unfortunately, evidence of a central circadian mechanism coordinating reproductive processes is currently fragmentary.

3.11.5.2. Circadian Regulation of Gamete Production

The existence of circadian rhythms in gametogenesis has received scant direct experimental attention. However, accumulating evidence of rhythmicity in the hormones that regulate gametogenesis, combined with substantial evidence that the output of mature gametes (at oviposition or mating) is also under circadian control, indicate that rhythmicity pervades the entire process of gamete production. Evidence of this view will be summarized prior to an examination of detailed rhythmic mechanisms in males and females below. There are three lines of evidence that are collectively compelling.

First, the evidence of circadian control of reproductive hormones is growing rapidly (see Section 3.11.5.1). The primary function of these hormones is regulation of gametogenesis. It would be surprising if rhythmicity in the secretion of regulatory hormones was not accompanied by rhythmicity in gametogenesis itself. The photoperiodic regulation of reproductive diapause (see **Chapter 3.12**) is a clear illustration that clock control of reproductive hormones is employed to regulate gametogenesis. It is firmly established that both JH and ecdysteroids exert a huge variety of actions on reproductive processes in both sexes (Hagedorn, 1985, 1989; Koeppe *et al.*, 1985; Wyatt and Davey, 1996; De Loof *et al.*, 2001) (see **Chapter 3.9**); therefore, there are numerous potential pathways by which rhythms in these hormones could evoke rhythmicity in egg or sperm production. For example, JH regulates vitellogenin production by the fat body and its uptake by the ovary, and in males it is involved in the regulation of accessory gland functions and affects reproductive behavior and spermatogenesis. Ecdysteroids are produced by both testes and ovaries (Gillott, 1995) and are regarded as possible insect sex steroid hormones (De Loof *et al.*, 2001). In females, ecdysteroids promote cell growth in egg follicles and in Diptera they regulate vitellogenin synthesis by both fat body and ovary. In males, ecdysteroids promote cell divisions in spermatocytes. Rhythmicity in any of these hormonal control pathways would likely lead to rhythmicity in gamete production.

Second, the discharge of mature eggs or sperm from the animal is frequently under circadian control. For example, the oviposition of mature eggs is often regulated by a circadian clock as is the mating activity of males (see Section 3.11.5.4.3). These behavioral rhythms require the presence of mature gametes at appropriate times of the day. The necessary coordination between these behavioral rhythms and gametogenesis could be achieved most directly by circadian control of gametogenesis.

Third, cyclic expression of the clock gene *per* has been reported in both ovaries and testes. In both ovarian follicle cells (Hardin, 1994; Hall, 1998) (see Section 3.11.5.2.1) and vas deferens epithelial cells (Gvakharia *et al.*, 2000) (see Section 3.11.5.2.2), *per* is expressed in a cycling fashion in LD but fails to free-run in DD or LL. These experiments are described in detail later. In other words, *per* cycles but not with the circadian properties that are required of a true clock. Such behavior of *per* is characteristic of oscillators that require a driving input (see Section 3.11.3.3 and **Chapter 4.11**). This requirement for a driving input to sustain *per* cycling in the reproductive system is further evidence of daily, rhythmic inputs to the system, most probably from rhythms in reproductive hormones. Hormones are well known as agents that entrain oscillators in vertebrates (review: Balsalobre, 2002) (see Section 3.11.3.3), and also in insect development (Steel and Vafopoulou, 1999) (see Section 3.11.4.1.4).

The above considerations lead to a testable model for the circadian regulation of gametogenesis. We suggest that a central timing system (in the brain?) controls the rhythmic release of neuropeptides that regulate rhythms in JH and/or ecdysteroids. JH and/or ecdysteroids provide the driving input to a *per*-based oscillator in the reproductive system, leading to rhythmic formation of gametes. Such a rhythm of gamete formation would be synchronized with rhythmic transport of eggs or sperm through the ducts of the reproductive system. These rhythms serve to make mature eggs and sperm available rhythmically for oviposition and mating behaviors,

respectively. These behaviors are themselves frequently rhythmic and under circadian control. This synchrony with behaviors implies action of JH and/or ecdysteroids on the nervous system, where they could act as modulators of the neural pattern generators for reproductive behaviors. Synchrony with behavioral rhythms could also be achieved centrally, by coupling of the putative neuroendocrine clock with the locomotor clock in the brain. Circadian rhythmicity potentially pervades reproductive mechanisms at all levels and in both sexes. Some of the known mechanisms are described below.

3.11.5.2.1. Oogenesis and egg transport Early studies with *Drosophila* by Allemand (1976a, 1976b) raised the possibility that oogenesis was rhythmic. Daily variations were reported in the frequency of egg chambers in various stages of development. These observations were interpreted as a daily rhythm in vitellogenesis, specifically in the time of onset of vitellogenic stages 8–10. The rhythm free-ran in DD for at least 5 days, implying that vitellogenesis (or at least some aspect of it), was under circadian control. Supporting evidence of such an "ovarian clock" derives from the localization of *per* transcripts and PER protein in the follicle cells surrounding small previtellogenic oocytes of *Drosophila*. However, this ovarian *per* transcript did not cycle (Hardin, 1994) and the PER protein was exclusively cytoplasmic, showing no cyclic migration to the nucleus (Liu *et al*., 1988; Saez and Young, 1988). This unclocklike behavior of *per* argues against the presence of a true clock involving *per* in the follicle cells (Hall, 1998). However, the notion of an oscillator residing within the follicle cells merits further exploration partly because it is these cells that synthesize ecdysteroids in many adult insects (Hagedorn, 1985, 1989). In addition, follicle cells are important targets of both JH (Wyatt and Davey, 1996) and ecdysteroids (Carney and Bender, 2000). Possibly, follicle cell oscillators are entrained by (rhythmic) hormonal signals and regulate rhythmicity in vitellogenesis by the oocyte that they surround. In other words, a follicle cell oscillator could be part of a pathway by which rhythmic endocrine signals lead to a rhythm in vitellogenesis.

Rhythmic mating can also lead to rhythmic egg development, again through endocrine pathways. As in many insects (see Section 3.11.5.4.2), mating in *Drosophila* is rhythmic and under circadian control (Sakai and Ishida, 2001). Mating accelerates egg maturation in *Drosophila*. After mating, there is an acceleration of yolk protein accumulation in the developing eggs, so that a large number of mature eggs is available for insemination. The sex peptide that is transferred to females by males at mating (see **Chapter 1.5**) is responsible for enhanced transcription of yolk proteins in the ovary, for enhanced yolk protein uptake by the ovary (Soller *et al*., 1997), and also for ovulation (Ottiger *et al*., 2000). These effects of sex peptide can be simulated by methoprene application (Soller *et al*., 1999). Sex peptide has also been shown to stimulate JH biosynthesis (Moshitzky *et al*., 1996). Mating also affects ecdysteroid levels, which affect vitellogenin synthesis by both ovary and fat body (Harshman *et al*., 1999; Soller *et al*., 1999). Therefore, rhythmic mating activity could readily lead to rhythmic changes in both JH and ecdysteroid levels and consequential rhythmic stimulation of vitellogenesis.

In many species, oviposition occurs with a circadian rhythm (see Section 3.11.5.4.3). The time interval between ovulation and oviposition is often both constant and quite brief, implying that rhythmic oviposition may be synchronized with, or may even be a consequence of, rhythmic ovulation. The rhythmic removal of eggs from the reproductive system requires that mature eggs are available for oviposition at circadian intervals. The simplest and most efficient mechanism by which this could be achieved would be by circadian regulation of egg maturation.

The control of ovulation and oviposition involves a multiplicity of hormones acting in species-variable patterns (Nijhout, 1994). The factors that regulate contractions of the oviducts have been extensively studied in *L. migratoria* (Donini *et al*., 2001). In this insect, transverse nerves, the caudal sympathetic system, and local neurons innervate the oviducts. Numerous hormones and neurotrasmitters such as CCAP, FMRF-related peptides, proctolin, glutamate, and octopamine are all involved in regulation of the oviduct contractions. The orchestration of these various factors into the observed circadian rhythm of oviposition has not yet been examined in any insect.

3.11.5.2.2. Spermatogenesis and sperm transport In the male reproductive system, circadian involvement has been demonstrated clearly in the duct system that transports sperm, but not in spermatogenesis itself. The absence of data does not imply that rhythmicity is absent; it could readily result from rhythmicity in the endocrine factors that regulate spermatogenisis. Both JHs and ecdysteroids regulate spermatogenesis in a complex and apparently species-variable manner (Dumser, 1980; Hagedorn, 1985; Koeppe *et al*., 1985; Hardie, 1995; Wyatt and Davey, 1996). For example, it has been shown that both hormones act directly on the testis where they regulate rates of cell division at specific stages

of spermatogenesis. In *B. mori*, JH affects the rate of division in spermatocytes (Kajiura *et al*., 1993). Ecdysteroids stimulate mitotic divisions in spermatogonia of *Rhodnius* (Dumser, 1980) and meiotic divisions in both *Manduca* (Friedländer and Reynolds, 1988) and the European corn-borer, *Ostrinia nubilalis* (Gelman *et al*., 1988). Thus, rhythms in ecdysteroids and/or JH (see Section 3.11.5.1) could result in rhythms of cell division in the testes. Also, other rhythmic inputs, such as mating, could impose rhythmicity on these endocrine control pathways and result in rhythmicity in spermatogenesis.

In several Lepidoptera, the movement of the sperm through the reproductive system is under circadian control. In stark contrast to the female system, it is alleged that neither nerves nor hormones are involved in the regulation of this movement (Giebultowicz, 2000). In Lepidoptera, sperm that are released from the testis are transported along the vas deferens by muscular contractions as aggregates known as bundles. These bundles may remain intact until after mating. In whole animals or isolated abdomens of *P. gossypiella* and *Ephestia* (*Anagasta*) *kuehniella* and *Spodoptera litura*, the sperm bundles move along the ducts in a series of distinct steps that is repeated as a daily rhythm (Riemann and Thorson, 1971; Riemann *et al*., 1974; LaChance *et al*., 1977; Thorson and Riemann, 1977; Seth *et al*., 2002). This rhythmic movement of sperm bundles was also found in *Spodoptera littoralis* and *Lymantria dispar*, using *in vitro* incubations of organ complexes which contained the testis and upper vas deferens (UVD) and in some instances the seminal vesicle (SV) as well (Giebultowicz *et al*., 1988; Bebas *et al*., 2001). This rhythm of bundle transport free-ran in DD and was phase-shifted by light cues *in vitro* showing that a clock that controls the rhythm of transport resides within the reproductive system. A rhythm of sperm transport is also seen in *E. kuehniella* and *Cydia pomonella in vivo*, but fails to persist *in vitro* (Bebas *et al*., 2001); in these species it appears that rhythmicity in sperm transport is driven by factors outside the reproductive system.

Thus, in some moths, the reproductive system contains a photosensitive circadian clock that regulates rhythmic transport of sperm. The literature refers to this as a rhythm in "sperm release," in which the liberation of sperm from the testis and their subsequent movement by the ducts are considered as two component steps of a single rhythmic event. If correct, this view requires that liberation of sperm from the testis is also rhythmic, a phenomenon that suggests rhythmicity in spermatogenesis itself. However, studies of the "sperm release rhythm" generally involve only studies of transport and not of release itself. Consequently, the contribution of rhythmic sperm release from the testis to the observed rhythmic movement of sperm along the ducts is unknown. However, these two processes are influenced differentially by ecdysteroids (see below), suggesting that they should be regarded as distinct events.

As mentioned above, translocation of sperm from the testis along the ducts results from muscular contractions of the wall of the UVD. The UVD of *Ephestia* consists of layers of longitudinal and circular muscle and a single cell layer of inner epithelium (Riemann and Thorson, 1976). The nerve supply to the vas deferens is abundant and evident in the lower part, and sparse (but not absent) in the UVD (Riemann and Thorson, 1976; Thorson and Riemann, 1977). In *Lymantria*, structures resembling axons were seen between the circular muscle and the basement membrane of the UVD epithelium (Giebultowicz *et al*., 1996). Evidence of a local nerve supply is derived from analysis of the complex patterns of muscular contractions exhibited *in vitro* by the testis–UVD–SV complex (Giebultowicz *et al*., 1996). Several distinct patterns of contractions occur in the UVD, each of which requires coordination of contraction of the circular and longitudinal muscle layers. Further, abrupt switches between these patterns also occur. One of these contraction patterns was responsible for the mass transfer of sperm bundles down the UVD to the SV (Giebultowicz *et al*., 1996). The onset of this pattern could occur *in vitro*, showing that it was not driven directly from the CNS. This pattern commenced at the normal time of the day for sperm transfer *in vivo*, implying that the clock may control the daily time of switching between motor patterns in the UVD. The overall complexity of the contraction patterns as well as the abrupt switching between them both strongly imply the presence of local neural regulation. By contrast, the literature states that the musculature of the UVD appears to receive no innervation and that the changes in contractile pattern occur autonomously (Giebultowicz *et al*., 1996). The functional requirements for the transport of sperm bundles along the male ducts are basically the same as those for transport of eggs along the female ducts. The importance of the local nerve supply employing a multitude of neurotransmitters has been well documented for control of the movement of eggs along oviducts (Orchard and Lange, 1988; Donini *et al*., 2001) (see Section 3.11.5.2.1). Therefore, we suggest that transport of sperm bundles is regulated by a

currently unidentified local nerve supply. Viewed in this light, the mechanisms of gamete transport in the male system become more comparable to those of the female system than the current literature suggests.

The location of the clock that controls the rhythmicity of sperm transport is unclear. In *C. pomonella* both *per* transcripts and PER were localized to epithelial cells lining the UVD wall. Both transcript and protein cycled in LD, but the *per* transcript showed "statistically insignificant" fluctuations in DD and the rhythm was "disrupted" in LL (Gvakharia *et al.*, 2000). It should be recalled that this behavior of *per* is very similar to that seen in the ovaries, where it was dismissed as unclocklike (Hall, 1998) (see Section 3.11.5.2.1). Such *per* oscillations that are not self-sustaining are characteristic of peripheral oscillators, that are driven by rhythmic inputs such as hormones (see Section 3.11.3.3), as has been argued for the ovarian *per* oscillator (see Section 3.11.5.2.1). The epithelial UVD oscillator seems unlikely to represent the clock that controls sperm transport since (1) the oscillator is not self-sustaining (i.e., does not free-run), whereas the rhythm in sperm transport does free-run, and (2) there is no known pathway or mechanism by which epithelial cells could regulate patterns of contraction by the overlying layers of muscles. We conclude that the epithelial oscillator likely regulates activities of the epithelial cells themselves but is not the clock that regulates rhythmic sperm movement. Indeed, these epithelial cells exhibit rhythmic secretion into the duct lumen (Riemann and Giebultowicz, 1991; Giebultowicz *et al.*, 1994) and regulate the rhythmic acidification of the lumen (Bebas *et al.*, 2002), which contributes to the maturation of sperm in the UVD (Riemann and Thorson, 1976).

The organ system used above *in vitro* to study rhythmicity in sperm movement consisted of most of the reproductive system including the testis, which is the largest endocrine organ in adult males. The testis is the only confirmed site of ecdysteroid synthesis in adult male moths (Loeb *et al.*, 1984, 1988). Sperm movement from the testis into the vas deferens was temporarily inhibited by the injection of 20E into adults of *Anagasta* (Thorson and Riemann, 1982) or infusion of 20E into pharate adults of *Lymantria* (Giebultowicz *et al.*, 1990), both in a dose-dependent manner; higher doses of 20E produced greater inhibition. The effectiveness of injections of 20E into pharate adults of *Lymantria* decreased as development proceeded, suggesting that a decline in the ecdysteroid titer was necessary for the initiation of sperm transport. However, Thorson and Reimann (1982) had shown earlier that 20E injection into isolated abdomens of adults of *Anagasta* also inhibited sperm transport, even though the normal decline in ecdysteroids titer was complete in these animals. These authors reported that the inhibition of sperm release by injected 20E did not appear to be due to inhibition of spermatogenesis because there was an accumulation of unreleased eupyrene sperm cysts at the junction of the testis and UVD in animals injected with 20E. Interestingly, the release of apyrene sperm was unaffected. Further, the rhythm of transport of sperm down the UVD was also unaffected by 20E (**Figure 22**). These differential actions of 20E on sperm release and sperm transport suggest that these two processes may represent separate distinct rhythms. It is possible that at least some of the reported events occuring in the testis–UVD–SV complex *in vitro* could be affected, or even caused, by ecdysteroids released from the testis *in vitro*. It seems important to examine the moth testis for rhythmicity in ecdysteroid synthesis, since this could drive rhythmicity in various events associated with sperm release and transport. This organ system is also potentially the source of a plethora of neurotransmitters, neuromodulators, and hormones from unidentified tissue adhering to the reproductive system, as is the case with the female system. It is therefore likely that a local nerve supply, various neuropeptides, neuromodulators,

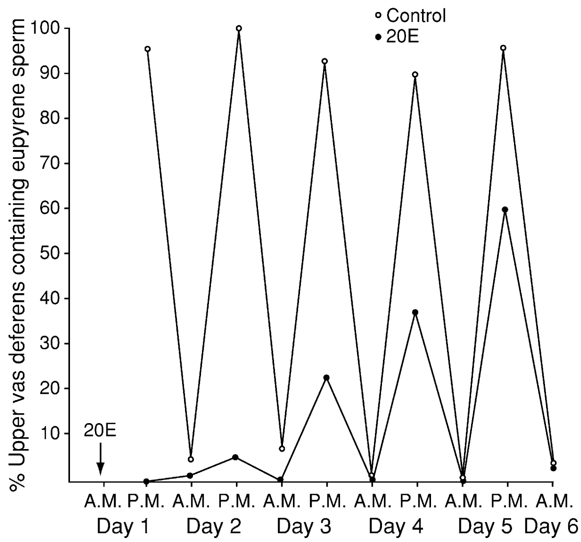

Figure 22 Injection of 20E into isolated abdomens of *Anagasta kuehniella* temporarily reduced the number of eupyrene sperm released into the upper vas deferens, but did not appear to affect the daily rhythm of sperm release. (Reprinted with permission from Thorson, B.J., Riemann, J.G., **1982**. Effects of 20-hydroxyecdysone on sperm release from the testes of the Mediterranean flour moth, *Anagasta kuehniella* (Zeller). *J. Insect Physiol. 28*, 1013–1019; © Elsevier.)

and ecdysteroids all interact to regulate the timing of sperm movement.

The time during adult development at which the clock that controls rhythmic sperm transport becomes operational was examined in *Lymantria* (Giebultowicz and Joy, 1992). At various times during adult development, pupae were transferred from LD to DD, or given a light pulse in DD. Pupal day 6 was found to be the earliest day on which a light cue could initiate rhythmicity in sperm release, i.e., 2 days before sperm transport normally commences. However, this is also the time of peak ecdysteroids in the hemolymph (Giebultowicz *et al.*, 1990) as well as the testis (Loeb *et al.*, 1984, 1988), suggesting that the clock becomes functional in the presence of ecdysteroids. In an attempt to determine if 20E interacted with the clock in the reproductive system 10–20 μg 20E were injected into animals that were maintained in LD (Giebultowicz *et al.*, 1996). Appearance of sperm in the UVD was abolished for 1 day but then resumed, as previously found in isolated abdomens of adult *Anagasta* by Thorson and Reimann (1982). It was inferred from this experiment that 20E does not affect the phase of sperm release. However, it is unlikely that any phase shift could be produced by 20E in this experiment due to the presence of simultaneous but conflicting light entrainment of the rhythm.

Some general conclusions can be drawn from the above studies with the male system. Sperm bundles are transported through the male duct with a circadian rhythm under the control of a photosensitive clock that probably acts on the muscles via a local nerve supply. Sperm release from the testis may also be rhythmic and possibly regulated by ecdysteroids, even *in vitro*. The *per*-based oscillator in the UVD epithelium regulates rhythmic secretion by these cells and seems to be a driven oscillator, possibly entrained by ecdysteroids. This system offers valuable opportunities for the study of interactions between nerves and hormones in the regulation of peripheral oscillators. The shortage of information regarding nervous and hormonal regulation is not an evidence that the clock is autonomous.

3.11.5.3. Rhythmic Neuroendocrine Control of the Sex Pheromone Signaling System

Communication between the sexes prior to mating may be performed by visual, auditory, or chemical (pheromonal) signals. The use of sex pheromones is widespread among insects (see **Chapter 3.14**). Sex pheromones are a heterogeneous collection of small, volatile chemical compounds, which may be released by either sex (usually by the female) depending on the species, to advertise sexual receptivity and availability. Sex pheromones vary greatly among species and there are extensive studies of their chemical composition, pathways and sites of biosynthesis in various insect groups (see **Chapters 3.14** and **3.15**). A common site of pheromone synthesis is the pheromone gland, but there are notable exceptions (e.g., in Diptera). Release of sex pheromones is achieved when the advertiser displays a characteristic pattern of sexual behavior called "calling," which involves a repertoire of body movements that expose the gland to the air and facilitate dispersal of pheromone in the environment.

In almost all insect groups with a long adult life, including cockroaches, beetles, Diptera, and moths, both the behavior of calling and the accompanied release of sex pheromones occur with a daily rhythm. The females of the brown-banded cockroach, *Supella longipalpa*, for example, engage in nightly rhythmic calling behavior during which they release volatile sex pheromone; the calling rhythm is truly circadian since it free-runs in both DD and LL and is phase-set by light (Smith and Schal, 1991). Release of pheromone with a daily periodicity has also been shown in several female beetles including the scarab beetle *Anomala albopilosa* (Leal *et al.*, 1996) and the bruchid beetle *Callosobruchus maculatus* (Shu *et al.*, 1996). In some flies, the males release sex pheromones and the females respond to them. Sex pheromones in Diptera are synthesized by abdominal oenocytes and then are deposited onto the surface of the cuticle following transportation via the hemolymph to epidermal cells (Tillman *et al.*, 1999). In males of the Caribbean fruit fly, *Anastrepha suspensa*, a daily rhythm in the amount of sex pheromone circulating in the hemolymph was observed, which suggested possible daily changes in synthesis (Teal *et al.*, 1999b). These daily variations in the level of sex pheromone in the hemolymph correspond closely with the daily rhythms of calling and pheromone release (Nation, 1990; Epsky and Heath, 1993). The response of females to the release of sex pheromones by males is also rhythmic in other Diptera, such as *Rhagoletis ceraci* (Katsoyannos, 1982), *Culex quinquefasciatus* (Jones and Gubbins, 1979), and *Musca domestica* (Sybchev *et al.*, 1986) and this is usually taken to signify the occurrence of rhythmic pheromone release by the males.

Moths are the most widely studied group for rhythmicities in both calling behavior and pheromone production/release. In moths, the pheromone glands are usually located beneath the intersegmental membrane between the 8th and 9th posterior abdominal segments and they often form extrusible sacs (Bjostad *et al.*, 1987). These sacs do not usually have reservoirs for pheromone storage, so that release follows synthesis quickly. Release usually

occurs as a result of calling behavior, which facilitates the exposure of the pheromone gland. However, in some Lepidoptera such as *Bombyx*, reversal of the heartbeat causes changes in the hemolymph pressure, which results in eversion of the gland and pheromone dispersal (Ichikawa and Ito, 1999). In moths calling occurs rhythmically every day until mating. Mating then inhibits calling behavior either temporarily or permanently. Numerous studies have documented daily rhythms in calling and regulation of the rhythm by an endogenous circadian clock. In *Lymantria*, calling occurs with a daily rhythm which is abolished in LL but reinstated by transfer back to DD (Webster and Yin, 1997). In the tiger moth, *Holomelina lamae*, the calling rhythm free-runs in both DD and LL, but damps out quickly in LL. Reintroduction of LD reentrains the rhythm (Schal and Cardé, 1986) (**Figure 23**). Rhythmicity in calling was abolished when these moths were reared in DD from the second instar onwards. When these DD moths were grouped according to the time of eclosion, the authors were able to detect a clear rhythm. This suggests that the clock that controls the calling rhythm may be phase-set at ecdysis. Temperature compensation of the calling rhythm was seen in *Congether punctiferalis* (Kaneko, 1986). Circadian rhythms in calling behavior were also seen in *Heliothis armigera* (Kou and Chow, 1987), *Pseudaletia unipuncta* (Delisle and McNeil, 1987), *Helicoverpa assulta* (Kamimura and Tatsuki, 1993, 1994), and *Manduca* (Itagaki and Conner, 1988). It therefore appears that in moths rhythmicity in the behavior of calling is a widespread, if not universal, phenomenon which is governed by an endogenous circadian clock mechanism.

The striking periodicity of calling behavior in moths implies that pheromone production/release is also rhythmic. Indeed, many studies have shown

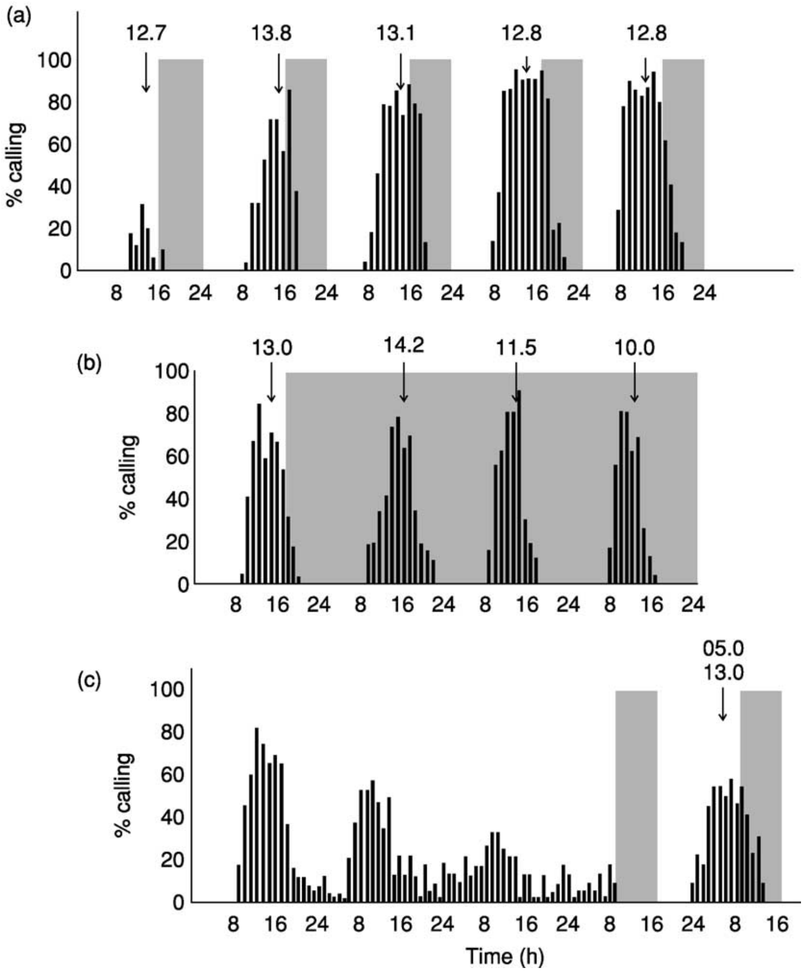

Figure 23 Entrained rhythm of calling behavior of females of the tiger moth, *Holomelina lamae* (Freeman) (a). The rhythm free-runs in DD (b) and damps out after a few cycles in LL (c). Reintroduction of the light cycle reestablishes the rhythm (right end of c). (Reproduced with permission from Schal, C., Cardé, R.T., **1986**. Effects of temperature and light on calling in the tiger moth *Holomelina lamae* (Freeman) (Lepidoptera: Arctiidae). *Physiol. Entomol. 11*, 75–87; © Blackwell Publishing Ltd.)

clear, circadian rhythmicities in pheromone content of the gland and/or pheromone release. Frequently, a close temporal relationship is found between daily changes in content of the gland, release of pheromone, and calling. For example, in the diurnal moth *L. dispar*, the pheromone content of the gland (Tang *et al*., 1992), the rate of pheromone emission from the gland (Charlton and Cardé, 1982), and the calling behavior (Webster and Yin, 1997) all exhibit synchronous daily rhythms with maxima in photophase and minima in scotophase. In the nocturnal moth *H. virescens*, the daily rhythmic changes in content of the gland (Rafaeli and Soroker, 1989; Mbata and Ramaswamy, 1990) and emission from the gland (Pope *et al*., 1982) are also synchronous, but occur with peaks in the scotophase and troughs in the photophase. In *H. assulta*, the quantities of all five individual components of the moth's pheromone cocktail in the gland fluctuated rhythmically during the day (Choi *et al*., 1998a) (**Figure 24a**) in synchrony with the calling rhythm (Kamimura and Tatsuki, 1993). Circadian control of rhythmicity was also shown in *Pseudaletia* (Delisle and McNeil, 1987), *Adoxophyes* spp. (Kou, 1992), *Agrotis segetum* (Löfstedt *et al*., 1982), *Bombyx* (Kuwahara *et al*., 1983; Sasaki *et al*., 1984), *Choristoneura fumiferana* (Ramaswamy and Cardé, 1984), *Mamestra brassicae* (Noldus and Potting, 1990; Iglesias *et al*., 1999), *Phthorimaea poerculella* (Ono *et al*., 1990), *Platynota sultana* (Webster and Cardé, 1982), *Sesamia nonagrioides* (Babilis and Mazomenos, 1992), and *S. littoralis* (Dunkelblum *et al*., 1987). In *Epiphyas postvittana* (Foster, 2000), rhythmicity in the pheromone content of a gland with no reservoir appears to result solely from periodic changes in pheromone synthesis, which is tightly coupled to release; there is no evidence of rhythmic degradation.

Thus, rhythmicity in the release of sex pheromone seems to be regulated directly at the level of synthesis. This fact implies that the factors that regulate synthesis may also be rhythmic (see Sections 3.11.5.3.1 and 3.11.5.3.2). However, there are some notable exceptions; in *Trichoplusia ni* release of pheromone occurs rhythmically (Sower *et al*., 1970), but pheromone production and release are not synchronous (Hunt and Haynes, 1990). Rather, synthesis of pheromone appears to be continuous and the daily rhythmicity in content of the gland results from rhythmic release caused by rhythmicity in abdominal movements during calling. Thus, circadian regulation of pheromone release in *Trichoplusia* may be driven by a clock governing behavior rather than a clock that regulates pheromone synthesis.

The synchrony of the pheromone release rhythm with the behavioral rhythm and their common responses to light manipulations suggest that they share common components in the underlying circadian clock mechanism. In other words, the pheromone clock and the behavioral clock may be closely linked. The clock for the calling rhythm and possibly that for the pheromone rhythm appear to be entrained by a brain photoreception center in *Andevidia peponis* (Sasaki *et al*., 1987). Surgical removal of both compound eyes and ocelli did not interfere with the ability of the calling rhythm to respond to phase shifts of the LD cycle. Localized illumination of various regions in the brain with 100 μm fiber optic light guides revealed that such phase shifts were induced by illumination of the mediodorsal protocerebrum near the medial neurosecretory cells. Illumination of other brain areas, including the optic lobes, was ineffective.

3.11.5.3.1. Rhythmicity in hormonal regulation of pheromone production The head is required for both pheromone production and calling behavior. Decapitation of females of the nocturnal moth *S. littoralis* either at the onset of a scotophase prior to the nocturnal peak of pheromone production or at the preceding photophase abolished both the production of pheromone and calling behavior (Martinez and Camps, 1988). Injection of an extract from the brain–SEG–retrocerebral complex restored both pheromone production and calling behavior equally well when administered either in the scotophase or photophase, but did not restore rhythmicity to either process. These findings imply that the expression of the pheromone release rhythm by the gland is dependent on the continuous presence of the head. Apparently the pheromone rhythm depends on circadian input from the head. The obvious implication was that the head contained a factor(s) that was essential for driving the oscillations of the overt pheromone rhythm.

A head factor with pheromonotropic activity (PBAN) was eventually identified in many moths (Raina and Klun, 1984; Martinez and Camps, 1988; Rafaeli and Soroker, 1989; Raina *et al*., 1989; Ma and Roelofs, 1995; Zhu *et al*., 1995; Zhao *et al*., 2002) and was subsequently isolated and characterized as a small, 33–34 amino acid neuropeptide with an amidated C-terminus (see also **Chapters 3.14** and **3.15**). PBAN has been sequenced in *Bombyx* (Kitamura *et al*., 1989), *Helicoverpa zea* (Raina *et al*., 1989), and *Lymantria* (Masler *et al*., 1994) and deduced from cDNA sequences in *A. ipsilon* (Duportets *et al*., 1998), *H. assulta* (Choi *et al*., 1998b), *Mamestra* (Jacquin-Joly *et al*., 1998),

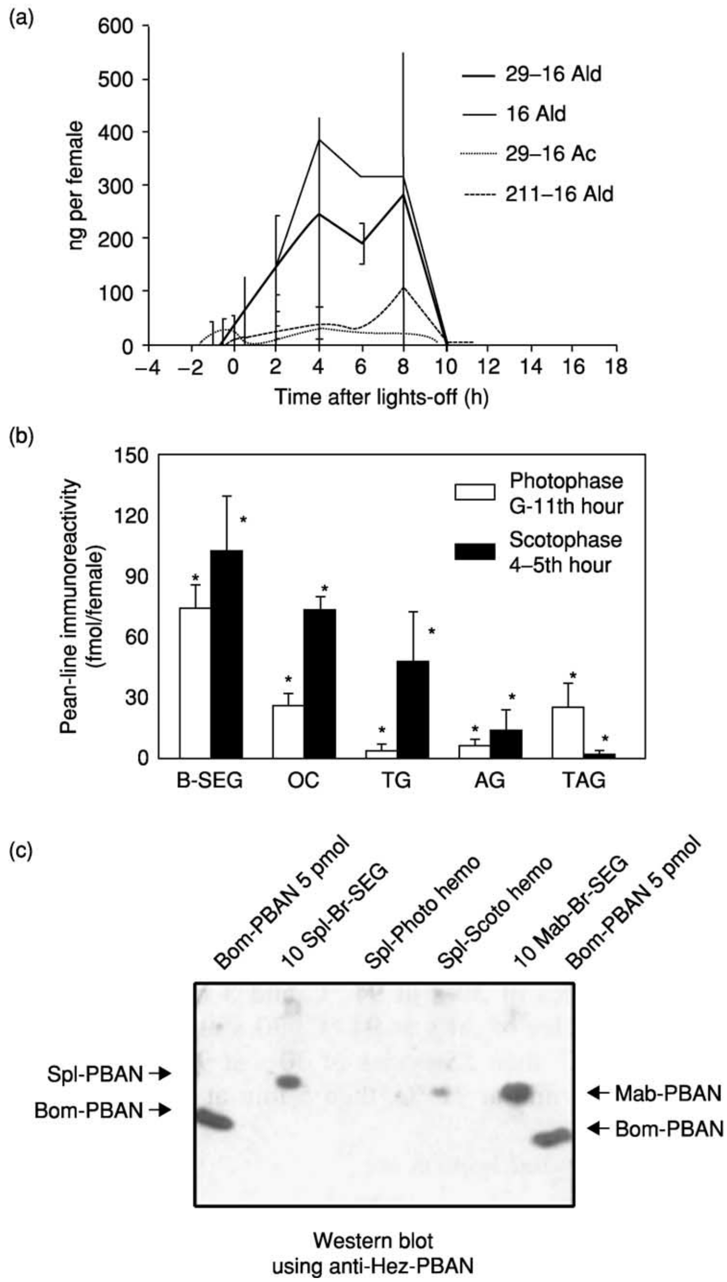

Figure 24 Daily rhythm of the five pheromone components in the pheromone gland of day 1 females of the tobacco budworm, *Helicoverpa assulta* in a 15 h light : 9 h dark cycle. (b) Day and night differences in the level of PBAN-like immunoreactivity in several neural tissues of females of *Helicoverpa armigera*. B-SEG indicates brain–subesophageal ganglia complex; CC, corpus cardiacum; TG, prothoracic ganglia; AG, abdominal ganglia, excluding the terminal abdominal ganglion (TAG). (Rafaeli, A., Hirsch, J., Soroker, V., Kamensky, B., Raina, A.K., **1991**. Spatial and temporal distribution of pheromone biosynthesis-activating neuropeptide in *Helicoverpa* (*Heliothis*) *armigera* using RIA and *in vitro* bioassay. *Arch. Insect Biochem. Physiol. 18*, 119–129; © Wiley. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.) (c) Western blot showing the presence of a single immunoreacitve peptide to antibody against PBAN of *Helicoverpa zea* in the hemolymph of scotophase (Spl-Scoto hemo) but not photophase (Spl-Photo hemo) females of *Spodoptera littoralis*. The peptide is also present in brain–subesophageal ganglia complexes (Spl-Br-SEG) of *Spodoptera*. Controls, synthetic PBAN-I from *Bombyx mori* (Bom-PBAN) and Br-SEG extracts from *Mamestra brassicae* (Mab-Br-SOG). (Reprinted with permission from Iglesias, F., Marco, P., François, M.-C., Camps, F., Fabriàs, F., *et al.*, **2002**. A new member of the PBAN family in *Spodoptera littoralis*: molecular cloning and immunovisualization in scotophase hemolymph. *Insect Biochem. Mol. Biol. 32*, 901–908; © Elsevier.)

and *S. littoralis* (Iglesias *et al.*, 2002). All PBANs share a high degree of sequence homology, the C-terminal pentapeptide being the most conserved. In *Bombyx*, PBAN is synthesized as a preprohormone that is trimmed to several peptides posttranslationally; one of these peptides bears striking similarity to the *Bombyx* embryonic diapause hormone (Sato *et al.*, 1993), possibly suggesting common regulation for both diapause peptide and PBAN.

In two species of *Helicoverpa* and in *Ostrinia*, immunohistochemistry and assays for both biological activity and expression of the PBAN gene have identified small groups of nerve cells in the SEG as the primary (but not necessarily the only) (see Section 3.11.5.3.2) source of PBAN (Ma and Roelofs, 1995; Choi *et al.*, 1998b; Ma *et al.*, 1998, 2000). Mapping of the axonal pathways from the PBAN-immunopositive cells in SEG in *Bombyx* revealed connections to the corpus cardiacum (CC), which suggested that the material produced in these PBAN cells in SEG may be transported to the CC for release (Ichikawa *et al.*, 1995). PBAN activity in the CC was detected in several moths. In *Ostrinia*, removal of the retrocerebral complex (CC and CA) significantly reduced the production of pheromone by the gland (Ma and Roelofs, 1995). The CC also immunostained intensely for PBAN and CC extracts exhibited strong pheromonotropic activity in both *Helicoverpa* spp. (Rafaeli *et al.*, 1991) and *Ostrinia* (Ma and Roelofs, 1995). These findings implied that the CC is probably the site of release of PBAN into the hemolymph.

Clear daily fluctuations in the PBAN content of the CC were found using a radioimmunoassay (RIA) for PBAN and assays for biological activity. In *Helicoverpa armigera*, the level of PBAN in the CC was significantly higher in scotophase than in photophase suggesting that transport to CC and/or release of PBAN from the CC were rhythmic (Rafaeli *et al.*, 1991; Rafaeli, 1994) (**Figure 24b**). In contrast, the level of PBAN in brain–SEG extracts did not change during the course of a day, suggesting that PBAN synthesis may be continuous (Rafaeli *et al.*, 1991; Rafaeli, 1994). Similar observations were also made in *A. segetum* in which PBAN biological activity in the brain–SEG did not show daily changes (Rosén, 2002). The view that PBAN release from CC is rhythmic was strengthened by extracellular recordings of the action potentials in the NCC-V nerve of *Bombyx;* this nerve contains the axonal projections from the PBAN-producing cells in SEG to CC (Ichikawa, 1998). A clear daily rhythm of bursting firing activity was found. This pattern of firing is associated with the release of neuropeptide in many other systems. The rhythm of bursting firing was synchronous with both the daily rhythm of calling behavior and with the pheromone content of the gland. The bursting activity rhythm free-ran in both DD (**Figure 25a**) and LL (**Figure 25b**), revealing endogenous circadian control (Tawata and Ichikawa, 2001). Collectively, these findings indicate that release of PBAN into the hemolymph occurs with a daily rhythm that is under circadian control.

Daily cycling in PBAN-immunoreactivity and/or biological activity in the hemolymph has also been detected in several moths. In the hemolymph of calling females of *Heliothis zea*, a peptide fraction with PBAN activity was detected in scotophase

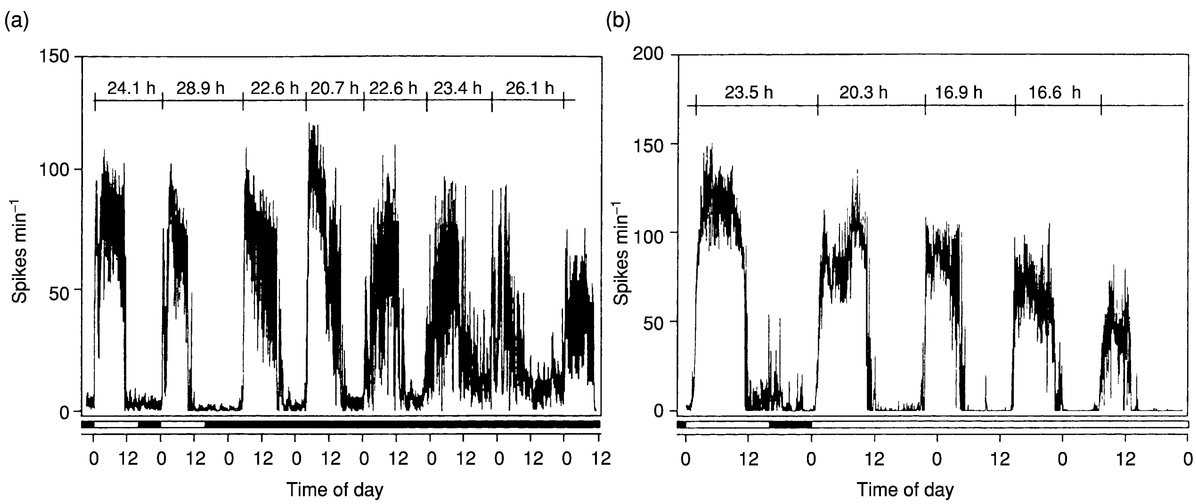

Figure 25 Entrained rhythm of the firing activity of the PBAN-producing cells, recorded from the nervus corporis cardiacum (NCC-V) of virgin females of the silkmoth, *Bombyx mori* (a). The rhythm free-runs in both DD (dark bar in a) and LL (light bar in b). (Reproduced with permission from Tawata, M., Ichikawa, T., **2001**. Circadian firing of neurosecretory cells releasing pheromonotropic neuropeptides in the silkmoth, *Bombyx mori*. *Zool. Sci. 18*, 645–649; © The Zoological Society of Japan.)

(Ramaswamy *et al.*, 1995) but not in photophase. Daily cycling of PBAN-like immunoreactivity was also detected in the hemolymph of females of *Mamestra*. This rhythm was also synchronous with the daily rhythms of pheromone production in the pheromone gland and calling behavior (Iglesias *et al.*, 1999). Similarly, in *S. littoralis*, Western blot analysis of hemolymph peptides of virgin females revealed the presence of PBAN-like compounds during the scotophase but not during the photophase (Iglesias *et al.*, 2002) (**Figure 24c**). In another moth, *A. segetum*, a bioassay for PBAN revealed that the hemolymph of females contained high PBAN activity in the scotophase but low in the photophase (Rosén, 2002). All these findings taken together support the view that at least in some moths, PBAN is released in the hemolymph where it exhibits a strong daily cycling. In the hemolymph, PBAN appears to function as a classical hormone, its principal target being the pheromone gland. Indeed, isolated pheromone glands were successfully stimulated by PBAN *in vitro* (Rafaeli and Soroker, 1989; Jurenka *et al.*, 1991; Matsumoto *et al.*, 1995; Zhao *et al.*, 2002). *In vitro* assays showed that PBAN acts on pheromone glands via a Ca^{2+}–calmodulin-dependent cyclase (review: Ramaswamy *et al.*, 1994), implying the presence of PBAN receptors on the surface of the pheromone gland cells. A putative cell membrane receptor for PBAN was identified recently in pheromone glands of *H. armigera* (Rafaeli and Gileadi, 1997; Altstein *et al.*, 1999, 2001). These findings imply that rhythmicity in the level of PBAN in the hemolymph drives rhythmicity in the production of pheromone by the pheromone gland.

However, there is a wide distribution of PBAN in the nervous system, and in some species the pheromone gland is directly innervated by the terminal abdominal ganglion (TAG). For example, the pheromone glands of two *Heliothis* species (Teal *et al.*, 1989, 1999a; Christensen *et al.*, 1991) and *Manduca* (Christensen *et al.*, 1994) are innervated from the TAG, whereas those in *Ostrinia* are not (Ma and Roelofs, 1995). PBAN immunoreactivity, gene expression (Rafaeli *et al.*, 1991; Ma and Roelofs, 1995; Ma *et al.*, 1998), and biological activity (Rosén, 2002) have been localized not only to the brain–SEG complexes and CC, but also to the thoracic and abdominal ganglia. In *H. armigera*, both PBAN immunoreactivity and biological activity cycled during a day in the thoracic and abdominal ganglia (Rafaeli *et al.*, 1991) (**Figure 24b**), suggesting possibly novel functional significance and circadian control. PBAN was also found in other neural sites. In *H. zea*, processes from the PBAN-positive cells in the SEG project into the ventral nerve cord (Kingan *et al.*, 1990). In *A. segetum*, PBAN activity was localized in the ventral nerve cord (VNC) where it fluctuated daily (Rosén, 2002). All the above raise the interesting possibility that there may be novel sites of synthesis and/or release of PBAN in the nervous system. Furthermore, the findings that PBAN and/or PBAN gene expression is found in males (Rafaeli *et al.*, 1993; Zhu *et al.*, 1995; Choi *et al.*, 1998b) and that putative PBAN receptors were located in thoracic muscles and the CNS (Elliot *et al.*, 1997) imply novel sites of action and functions of PBAN in addition to regulation of pheromone production in the pheromone gland. The significance of this information is at the moment unclear.

JH is also involved in the regulation of pheromone production as shown in the armyworm moth, *Pseudaletia* (Cusson and McNeil, 1989; Cusson *et al.*, 1994) and the black cutworm, *A. ipsilon* (Picimbon *et al.*, 1995) (see Section 3.11.5.1). Allatectomy at emergence inhibited pheromone production; injections of JH or CA extracts restored it. When females of the above species or of *H. armigera* (Fan *et al.*, 1999) were decapitated at emergence, injections of JH alone were ineffective in restoring pheromone production; however, injection of JH together with PBAN (or brain extract) restored it. This strongly suggested that the presence of JH was necessary for rhythmic, PBAN-dependent, pheromone production. The role of JH could be to regulate the production/release of PBAN by the brain–SEG (Cusson *et al.*, 1994; Picimbon *et al.*, 1995), or JH could be needed to prime the pheromone glands for the action of PBAN (Fan *et al.*, 1999). The latter may be achieved by upregulation of putative PBAN receptors in pheromone glands by JH (Rafaeli *et al.*, 2003). Either of these possibilities raises yet again the prospect that JH synthesis may be under circadian control. A fruitful line of enquiry would be the examination of JH levels in relation to rhythms of PBAN release and/or pheromone production.

3.11.5.3.2. Regulation of pheromone glands by rhythms in octopamine In moths where the pheromone gland is innervated, there is considerable evidence that neural control from the VNC is essential for the regulation of pheromone production. Octopamine release by efferent neurons from the TAG to the pheromone gland was implicated as exerting stimulatory and/or inhibitory control over the gland and, by implication, regulating the daily rhythm of pheromone production. Transection of the nerves from the TAG to the gland inhibited

pheromone production in *Heliothis zea*, *H. virescens* (Teal *et al*., 1989, 1999a; Christensen *et al*., 1991, 1992, 1994), and *A. segetum* (Rosén, 2002). Electrical stimulation of the nerve connectives anterior to the TAG induced pheromone synthesis in females in photophase, a time when they are not normally engaged in pheromone production (Christensen *et al*., 1991, 1992). In these moths, intact nerve connections to the pheromone gland are essential for pheromone production. Octopamine induced pheromone production by the gland when it was injected into intact females in photophase (no pheromone synthesis) or isolated abdomens of females in scotophase with transected nerve connectives (inhibition of pheromone synthesis) (Christensen *et al*., 1991, 1992). In *H. zea*, the level of octopamine in the TAG exhibited daily cycling, which occurred in antiphase to the daily cycle of the octopamine level in the pheromone gland (**Figure 26**). In mid-photophase, the TAG contained more octopamine than the pheromone gland. However, a few hours prior to lights-off, the octopamine levels in these two locations changed swiftly; the level of octopamine in the TAG decreased sharply, whereas the level in the gland increased significantly. About 1–2 h after lights-off the octopamine levels in both the TAG and the pheromone gland returned to the mid-photophase levels. The increase in octopamine level in

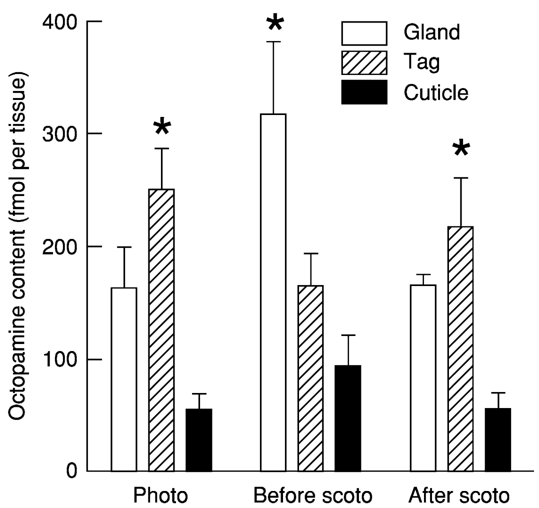

Figure 26 Day and night differences in octopamine levels in the pheromone gland, terminal abdominal ganglion (TAG), and abdominal cuticle (control) in females of *Heliothis zea*. ''Photo'' indicates mid-photophase; ''Before scoto'' indicates 0–2 h prior to lights-off; ''After scoto'' indicates 0–2 h after lights-off. Asterisks indicate statistically significant differences from controls. (Reprinted with permission from Christensen, T.A., Lehman, H.K., Teal, P.E.A., Itagaki, H., Tumlinson, J.H., *et al.*, **1992**. Diel changes in the presence and physiological actions of octopamine in the female sex-pheromone glands of *Heliothine* moths. *Insect Biochem. Mol. Physiol. 22*, 841–849; © Elsevier.)

the pheromone gland occurred at the time of pheromone emission and calling behavior. These findings provide strong circumstantial evidence that a rhythm in octopamine is involved in rhythmic pheromone synthesis. Experiments with administration of both octopamine and PBAN led the authors to suggest that the role of PBAN in the regulation of pheromone synthesis may be indirect. It was proposed that PBAN is transported to the TAG via the VNC, where it stimulates the octopaminergic innervation of the pheromone gland. However, Jurenka *et al.* (1991) and Ramaswamy *et al.* (1995) were unable to reproduce the above findings using the same moth and with the same experimental approach. It has also been proposed that octopamine may inhibit pheromone production. In *H. armigera*, octopamine or its agonist clonidine inhibited the pheromonotropic activity of PBAN using *in vitro* preparations of the pheromone gland (Rafaeli and Gileadi, 1997; Rafaeli *et al*., 1997), or *in vivo* in photophase animals that were injected with PBAN (Rafaeli *et al*., 1997). *In vivo*, the inhibition by octopamine or its agonist was reversed by injection of adrenergic antagonists only if the females were decapitated. Clonidine also inhibited normal pheromone increase in scotophase animals (Rafaeli *et al*., 1997). These findings led to the hypothesis that the daily declines during photophase in pheromone content of the gland may be attributable to daily inhibition of PBAN action mediated by octopaminergic receptors of the α_2-type.

3.11.5.4. Integration of Rhythmic Reproductive Behaviors with Hormones

The sequence of physiological processes that lead to the development of mature eggs and sperm is under complex endocrine control (see **Chapter 3.9**). Evidence of circadian regulation of these hormones is discussed above (see Section 3.11.5.1). Successful reproduction involves detecting and attracting a mate, copulation, and subsequent oviposition of fertilized eggs. In the context of hormones and circadian systems, these behaviors are significant in two ways, that may not be as distinct as the literature describes them. First, each of these behaviors occurs only at a temporally very precise part of the reproductive cycle, different behaviors being confined to different parts of the cycle. This point illustrates that the onset and termination of each behavior is intimately coordinated with the progress of egg and sperm development and therefore implies that the behaviors are modulated by signals from reproductive hormones. It further implies that different behaviors are executed in the presence of (and potentially influenced by) different hormonal

milieux. Second, all of these many distinct behaviors are performed rhythmically and are under circadian control. This point indicates integration between the reproductive hormones and the circadian system. The nature of this integration has received little experimental attention. The evidence summarized below indicates that it is unlikely that hormones directly drive reproductive behaviors. Rather, it appears that the clocks that drive behaviors are subject to sophisticated modulation by the endocrine milieu. For example, stridulation, courtship, mating, and oviposition all appear to be influenced by the locomotor clock (in the optic lobe) but each behavior takes place at a different time in the reproductive process. A model is envisaged in which the locomotor clock drives rhythmicity in the pattern generators for these behaviors, but which pattern generator becomes activated at any particular moment is influenced by the endocrine milieu. JH, octopamine, and various neuropeptides have been invoked as modulators of these behaviors, but much remains to be learned about how and where they act.

3.11.5.4.1. Rhythms in olfactory responses In many species, olfactory responses to odors (see **Chapter 3.15**) occur with a daily rhythm which is regulated by a circadian clock. The presence of a daily periodicity in olfactory responses is most apparent in the detection and response to sex pheromones. Successful mating depends on the daily coordination of the activities of males and females and it relies on temporal synchrony between the daily rhythm of release of sex pheromone by one sex (see Section 3.11.5.3) and the daily rhythm of responsiveness by the other. Daily rhythmicity in the behavioral rhythm of responsiveness to sex pheromones has been seen in a variety of insect groups including cockroaches (Liang and Schal, 1990), beetles (Shu *et al*., 1996), flies (Katsoyannos, 1982; Pivnic, 1993), and moths (Shorey and Gaston, 1965; Castrovillo and Cardé, 1979; Linn and Roelofs, 1992). The responsiveness rhythm is entrained by light cues in *Trichoplusia* (Shorey, 1966; Linn and Roelofs, 1992) and *Lymantria* (Linn *et al*., 1992), and free-runs in DD in *L. dispar* (Linn *et al*., 1992), *Trichoplusia* (Shorey, 1966; Lin and Roelofs, 1992), *Laspeyresia pomonella* (Castrovillo and Cardé, 1979), and the cockroach *Supella* (Liang and Schal, 1990), thus showing that it is controlled by an underlying circadian clock.

Circadian changes in responsiveness to sex pheromones could theoretically derive from circadian control over changes in olfactory sensitivity in the antennal sense organs or equally in the central processing of the olfactory input. Evidence suggests that both control mechanisms may in fact be operational in different insects. Explanted antennae of *Drosophila* incubated *in vitro* exhibited a daily rhythmicity in the expression of the *per* gene, which free-ran in DD for many cycles (Plautz *et al*., 1997); the rhythm was entrained by light *in vitro*. Electroantennogram responses of *Drosophila* to odorants such as ethyl acetate or benzaldehyde revealed a daily rhythm of responsiveness, which free-ran in DD and damped out quickly in LL (Krishnan *et al*., 1999). A *per* transgenic line (Krishnan *et al*., 1999) and *cry* mutants (Krishnan *et al*., 2001) confirmed that olfactory responses in *Drosophila* are controlled by a circadian clock residing in the antennae (**Figure 5**) (see Section 3.11.3.3). This antennal clock may be involved in the regulation of the rhythm of responsiveness to sex pheromones via regulation of the sensory neurons or binding proteins to pheromones that have been localized in the antennae of several insects (see **Chapter 3.15**).

A central mechanism in the antennal lobes appears to control the daily rhythmicity in pheromone sensitivity in the moth *A. ipsilon*, which is modulated by JH (Gadenne *et al*., 2001) (see Section 3.11.5.1). In addition, injection of octopamine affects many aspects of the responsiveness of male moths to sex pheromones, including the circadian rhythm of responsiveness (Linn *et al*., 1996; Linn, 1997). The complexity of octopamine effects on behavior suggests that octopamine may exert its influence on the male responsiveness by acting on the CNS. Experiments with phase advances and phase delays of the responsiveness rhythms showed that octopamine injections were effective only when administered within a narrow time window in the daily cycle prior to the daily peaks of responsiveness, suggesting a circadian component to the regulation of responsiveness by octopamine. In support of this notion is the finding that the levels of octopamine in the brain of *Trichoplusia* males exhibited a daily periodicity that was synchronous with the daily rhythm of responsiveness (Linn *et al*., 1996); the octopamine rhythm in the brain free-ran in DD and damped out rapidly in LL. All this implies that the mechanism of control of the responsiveness rhythm is centrally located and possibly related to the locomotor clock (Linn *et al*., 1996), whose output to the tritocerebrum may be modulated by circadian changes in octopamine.

There is also evidence that octopamine acts peripherally by modulating the sensitivity of the sensory neurons that detect sex pheromone in the antennae of males of *Antheraea polyphemus* (Pophof, 2000), *Mamestra* (Grosmaitre *et al*., 2001), and *Bombyx*

(Pophof, 2002). Octopamine receptors were cloned from the antennae of *Bombyx* and *H. virescens* and localized near the base of the olfactory hairs in *Heliothis* (Nickisch-Rosenegk *et al.*, 1996). The effects of octopamine on pheromone perception may thus be mediated by these antennal receptors; the modulatory action of octopamine may occur either at the level of generation of action potentials in the antennal receptor neurons (Pophof, 2002) or by acting on the accessory cells of the sensillum (Dolzer *et al.*, 2001). The olfactory receptor neurons in the antennae project axons directly into the antennal lobes, from whence projection neurons connect the antennal lobes with the lateral protocerebrum either directly or indirectly via the mushroom bodies (Heimbeck *et al.*, 2001; Hansson, 2002). *Drosophila* transgenic flies in which the function of these projection neurons was disrupted by transgenic expression of tetanus toxin show defects in both odor detection and courtship behavior of males (Heimbeck *et al.*, 2001). There is therefore a neural pathway that connects olfactory inputs with rhythmic behavioral outputs. In general, it appears that octopamine modulates the antennal olfactory clock whose output is integrated with the central locomotor clock. In turn, the outputs of the locomotor clock are responsible for driving various rhythmic behaviors such as upwind flight of the males, courtship, and mating. Further, JH appears to be involved in the modulation of the central neural pathways of the above rhythmic behaviors (see Section 3.11.5.1).

3.11.5.4.2. Bioluminescence, courtship song, and stridulation Several species, primarily Coleoptera, use bioluminescence for sexual attraction. The best-studied examples are the nightly displays of flashes of light by fireflies as a means of photic dialogue between the sexes. During flashing the animals are capable of emitting, receiving, and interpreting visual signals from the other sex. One sex, usually the male, emits a characteristic rhythmic pattern of light flashes during flight that is recognized by conspecific females; the females respond with an equally stereotyped pattern of flashes. In some firefly species, flashing by males may become synchronized in a local population of fireflies. In these synchronously flashing populations of males, the rhythmic pattern of flashing is self-sustained, runs with a stable free-running period, is entrained and phase-shifted to periodic pulses of light; therefore, it exhibits all the characteristics of an ultradian rhythm that is endogenously controlled (Buck, 1988). Flashing occurs with a circadian rhythm, within which there is a strong ultradian rhythm (Buck, 1988). Both rhythms are interrelated in terms of formal clock properties and physiological control (see below).

The efficacy of flashing as a mating signal depends also on the ability of females to receive and interpret rhythmic photic signals from the males. A daily rhythm in visual responsiveness to light flashes was observed in *Photuris versicolor* that free-runs in DD and is synchronized with the rhythm of flying and flashing (Lall, 1993). Therefore, the synchronous occurrence of all three rhythmic phenomena – bioluminescence, visual responsiveness, and flight – suggests that they may all be regulated by a common circadian clock. Indeed, it has been suggested that the ultradian flashing oscillator is associated with the locomotor clock in the brain (Bagnoli *et al.*, 1976; Case, 1984).

The regulation of courtship behavior in *Drosophila* provides another example of a behavior that has both circadian and ultradian properties. In wild-type flies of *Drosophila*, mating is preceded by courtship during which the male orients himself and directs auditory signals (the courtship song) towards the female by extension and vibration of the wings. One of the components of this song is a train of pulses with an interpulse interval that oscillates sinusoidally with a mean value of 55 s. This ultradian rhythm free-runs in LL and is temperature compensated; it is therefore regulated endogenously (Kyriakou and Hall, 1980). Mutations in *per* altered both this ultradian rhythm and the circadian locomotor rhythm. Construction of genetic mosaic flies for *per* showed that song phenotype was determined by expression of the *per* allele in the thoracic ganglia but not in the brain (Konopka *et al.*, 1996). The only cells that express *per* in the thoracic ganglia were glial cells (Ewer *et al.*, 1992). A general conclusion from both fireflies and *Drosophila* is that the oscillators for ultradian and circadian rhythms appear to share common components at both the cellular and anatomical levels.

Many insects also communicate using rhythmic acoustic signals produced by specialized structures. The best-known example is stridulation in crickets. In numerous species, stridulation is under circadian control. For example, in *Teleogryllus commodus*, stridulation occurs with a strong daily rhythm that free-runs in both DD and LL (Sokolove and Loher, 1975); it is, therefore, controlled by an endogenous circadian clock. In these species, removal of the eyes or severance of the eyes from the optic lobes results in a free-running rhythm of stridulation in either LD or LL, but with a period length characteristic of DD (Sokolove and Loher, 1975). These experiments are consistent with the view that the

stridulation rhythm is controlled by the same clock that controls the locomotor rhythm. Subsequent experiments showed that the stridulation rhythm could be uncoupled from the locomotor rhythm, but the clocks controlling both rhythms were both located in the optic lobes (Wiedenmann, 1983; Wiedenmann and Loher, 1984; Wiedenmann *et al*., 1988). It was suggested that each optic lobe contains two circadian clocks (one for each rhythm) that are normally coupled together.

3.11.5.4.3. Mating and oviposition Daily periodicities in mating behavior have been identified in all major insect groups. It is generally accepted that an endogenous circadian oscillator controls rhythmicity in mating, although there have been only a few true circadian studies. Endogenous circadian control of mating has been observed in beetles (Walker, 1979; Boucher and Pierre, 1988), fruit flies (Loher and Zervas, 1979; Sakai and Ishida, 2001), and moths (Han *et al*., 2000). In *Drosophila*, mating occurs with a circadian rhythm that free-runs in DD and is abolished in *per* and *tim* null mutants (Sakai and Ishida, 2001). Further, in *disconnected* mutants which lack some of the lateral clock neurons that control locomotion and have severe defects in the optic lobes, rhythmicity in mating was also abolished. Taken together, these observations showed that rhythmicity in mating behavior may be controlled by the locomotor clock. Thus, the *Drosophila* mating repertoire becomes an illustration of the fine coordination of clock-controlled mating activities between the sexes. Successful mating contact depends on olfactory responses of males to the release of female sex pheromones; these responses are controlled by a *per*-based olfactory clock in the antennae (Krishnan *et al*., 1999) (see Section 3.11.5.4.1). Males respond to the female chemical signal by performing the courtship song, which is also *per* controlled (Kyriakou and Hall, 1982) (see Section 3.11.5.4.2). Courtship song, in turn, affects female receptivity (Kyriakou and Hall, 1982; Hall, 2002). Thus it appears probable, as Sakai and Ishida (2001) suggested, that the mating rhythm in females may be a consequence of circadian control over pheromone release and/or responsiveness to male courtship song.

Oviposition behavior is also under circadian control in numerous insects, such as bugs (Ampleford and Davey, 1989), crickets (Sefiani, 1987), moths (Riedl and Loher, 1980; Bell, 1981; Yamaoka and Hirao, 1981; Shearer *et al*., 1995), flies and mosquitoes (Allemand, 1983; Joshi, 1996). The physiological links between mating and oviposition are both complex and species-variable (see **Chapter 1.5**). Peptides transferred to the female at mating have been shown to enhance fertility, promote oviposition, or inhibit further mating by the female (Kubli, 1992; Stanley-Samuelson, 1994). Further, proteinaceous material transferred to the female at mating can be utilized as nutrient to accelarate oogenesis; amino acids and proteins from the spermatophore have been detected in the eggs of many species (Huignard, 1983; Mullins *et al*., 1992). In some insects such as the tettigonids and crickets, the female feasts on the spermatophore whose peptide components can be found later in eggs (Simmons and Gwynne, 1993). Thus, the male contributes to both completion of egg development by the female and to the behavioral changes that follow mating. These points emphasize the close integration between the mechanisms that control egg and sperm development with those that control rhythmic behavior.

The circadian control of oviposition behavior must be synchronized with the presence and movement of eggs along the oviducts. Complex neuroendocrine mechanisms control the process of egg movement, extensively studied in orthopterans. There are pattern generators in the TAG for both digging (Thompson *et al*., 1999) and regulation of oviducal contractions (Kalogianni and Theophilidis, 1993), and contractions are influenced by proctolin, octopamine, and FMRFamide-related peptides (Noronha and Lange, 1997; Orchard *et al*., 1997). Despite extensive physiological analysis, the origin of circadian control of this system is unexplored.

3.12 Hormonal Control of Diapause

D L Denlinger, Ohio State University, Columbus, OH, USA
G D Yocum, Red River Agricultural Research Center, Fargo, ND, USA
J P Rinehart, Ohio State University, Columbus, OH, USA

3.12.1. Introduction

The evolution of diapause is arguably one of the most critical events bolstering the success of insects. Having the capacity to periodically shut down development has enabled insects and their arthropod relatives to invade environments that are seasonally hostile. Indeed, very few environments permit continuous insect development. Even in the tropics, where temperatures throughout the year may be compatible with poikilotherm development, season patterns of rainfall drive cycles of plant growth that favor insects with the ability to periodically become dormant.

Diapause is an arrest in development accompanied by a major shutdown in metabolic activity. Unlike a simple quiescence that is an immediate response to an unfavorable environmental condition, diapause is a genetically programmed response that occurs at a specific stage for each species. Sometimes the insect will enter diapause at this particular stage in each generation regardless of the environmental conditions it receives (e.g., pharate first instar of the gypsy moth *Lymantria dispar*), a developmental program referred to as an obligatory diapause. Much more frequently, the decision to enter diapause is determined by environmental factors, usually daylength, received by that individual or its mother at an earlier developmental stage. This is referred to as a facultative diapause.

Development can effectively be interrupted at many points, as evidenced by the rich diversity of developmental stages used by different species for diapause. Embryonic diapauses have been documented for nearly all possible stages of embryonic development, ranging from early blastoderm formation to pharate larvae. Larval diapauses are most common in late instars, but early instar diapauses are not at all uncommon. Pupal diapause is well documented, and a few species diapause as pharate adults, but, not surprisingly, there appear to be no instances where development is halted once pharate adult development has been initiated. The most prevalent cases of adult diapause involve newly emerged adults that have not yet reproduced, but there are also examples of diapause interrupting periods of reproduction. Most commonly, insects enter diapause only once during their life cycle, but some species, especially those living at higher latitudes, may extend their development over several years, and thus spend successive winters in diapauses of different stages. Some long-lived adults may also go through multiple diapauses to coordinate egg laying with favorable conditions.

The fact that diapause is programmed well in advance of its onset implies that there is a prediapause period that can be used to prepare the insect for the special conditions that lie ahead. Hence it is common for insects that are destined for diapause to have a somewhat prolonged period of prediapause development, attain a larger size, accumulate additional lipid reserves, and add additional waterproofing to their cuticle. Distinct coloration, often to

match the insect's overwintering environment, may accompany the entry into diapause. Insects entering a winter diapause frequently undergo metabolic adjustments to enhance cold hardiness. In some cases the cold hardiness is a component of the diapause program, but in other cases cold hardiness is invoked by a different set of environmental cues.

The term diapause perhaps falsely suggests a period of arrest in which development comes to a complete halt. The period of diapause should not be regarded as a simple stop and restart of development. Andrewartha (1952) originally coined the term "diapause development" to refer to the ongoing progression of events that occurs during diapause and eventually results in the termination of diapause. It is evident that diapause is a dynamic process, as evidenced by characteristic changes in the utilization of energy reserves, systematic changes in patterns of oxygen consumption, changes in responsiveness to environmental stress and hormones, and distinct patterns and changes in gene expression. A progression of events must transpire before diapause can be terminated. In some cases, development is not completely halted. There are several examples in which developmental processes continue during diapause, albeit at much slower rates, e.g., ovarian maturation during the adult diapause of the mosquito *Culex pipiens* (Readio *et al.*, 1999) and embryonic development during diapause in the pea aphid, *Acyrthosiphon pisum* (Shingleton *et al.*, 2003). In some cases there can be profound differences even within the body of a single individual. For example, during pupal diapause in the tobacco hornworm, *Manduca sexta*, most tissues of the body are arrested, but the testicular stem cells continue to undergo mitotic division (Friedlander and Reynolds, 1992). These unique events of diapause, coupled with prediapause distinctions in diapause-programmed individuals, suggest that it is perhaps most appropriate to view diapause as an alternate developmental pathway.

Comprehensive coverage of ecological aspects of insect diapause can be found in excellent reviews by Tauber *et al.* (1986) and Danks (1987), clock mechanisms are discussed in detail by Saunders (2002), and molecular aspects of diapause regulation are discussed by Denlinger (2002). The goal in this review is to highlight the major discoveries relevant to the hormonal control of diapause that have occurred subsequent to 1985. The earlier literature was covered previously (Denlinger, 1985), and in this review the earlier findings are briefly summarized and new developments in this field are emphasized.

3.12.2. The Preparative Phase

During the preparative phase, the insect must make the decision to enter diapause (and sometimes how long to remain in diapause) and make the accompanying alterations that will result in the sequestration of additional energy reserves and waterproofing agents, and initiate specific behavioral programs needed to find protected sites appropriate for overwintering. Some species, such as the Monarch butterfly, *Danaus plexippus*, engage in long-distance flights to reach their overwintering site, but more commonly, insects programmed for diapause migrate to buffered sites that are closer at hand. When diapause is viewed as an alternate developmental program, these phases unique to diapause, even if they occur prior to diapause, must also be viewed as part of the diapause syndrome.

These early distinctions underscore the fact that we can not simply focus on the endocrine events that dictate the onset and termination of diapause. A comprehensive view of diapause also calls for an understanding of the control mechanisms regulating these early events, but regrettably we know very little of the events that regulate early phases of this developmental pathway. For example, what endocrine signals direct a diapause-programmed flesh fly (Sarcophagidae) larva to sequester twice as much lipid as a larva not destined for diapause? This observation suggests that the set points for lipid accumulation differ in diapause- and nondiapause-destined individuals, a distinction most likely regulated by the endocrine system. What signals lead to formation of the extra layer of hydrocarbons that line the puparium of a flesh fly destined for diapause? A brain factor whose action can be mimicked with cAMP appears to be involved (Yoder and Denlinger, 1992), but its identity remains unknown.

3.12.2.1. Making the Decision to Enter Diapause

For an obligate diapause, the decision to enter diapause is hard-wired. Diapause will be entered at a specific stage regardless of the environmental conditions. This is an arrangement common to species that have single generation each year, e.g., the gypsy moth and the Cecropia silkmoth, although in both of these examples a few individuals fail to enter diapause. By contrast, a facultative diapause enables the insect to complete several generations per year, and the individual "decides" its own developmental fate based on the environmental cues it perceives. The plasticity of this arrangement offers flexibility and enables the insect to more closely coordinate development with the appropriate seasons. An

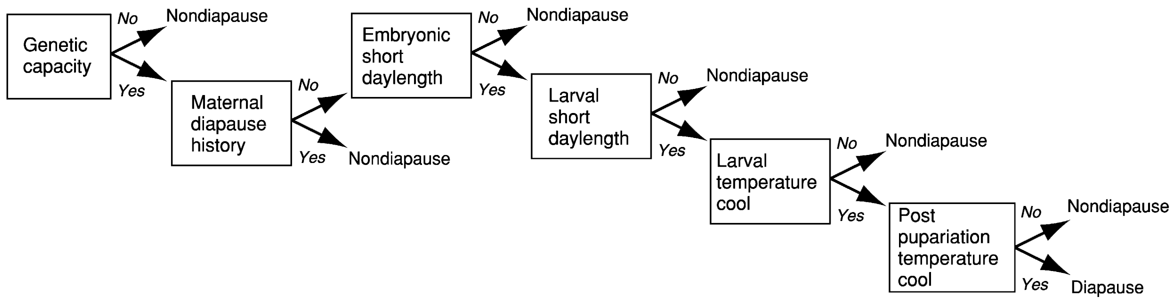

Figure 1 Sequence of signals required for the programming of pupal diapause in flesh flies (*Sarcophaga*). (Reproduced with permission from Denlinger, D.L., **1985**. Hormonal control of diapause. In: Kerkut, G.A., Gilbert, L.I. (Eds.), Comprehensive Insect Physiology, Biochemistry and Pharmacology, vol. 8. Pergamon Press, Oxford, pp. 353–412.)

additional variation of this theme is when the individual does not directly decide but the decision is made by the mother.

The decision to diapause should not be viewed as a simple "yes/no" decision made at a single moment in time, but rather it is the culmination of a series of events, as exemplified for the flesh fly example shown in Figure 1. This example shows that the programming of diapause can be averted at many points along the way, right up to the time that diapause is normally manifested. In order for the program to be enacted, all of the previous conditions must have been fulfilled. Thus, the diapause program can be aborted at the last minute, but attempts to induce diapause by offering the correct signals only during the later phases of development will not be sufficient to induce diapause.

3.12.2.1.1. Reading the environmental cues Short daylength, a reliable harbinger of winter, is the most common cue used for the programming of an overwintering diapause (Figure 2). The precision of this environmental token makes it a seasonal indicator of unparalleled reliability. The critical photoperiod, the transition point between photoperiods that elicit diapause and nondiapause development, is usually quite sharp, thus implying that insects can readily distinguish daylength differences as small as 15 min. Insects that enter a summer diapause may use long daylengths instead of short daylengths for the programming of diapause (Masaki, 1980), and there are numerous examples of photoresponse curves showing restricted portions of the curve to be diapause inductive. Daylength appears to be measured as a threshold character, and only a few examples suggest that insects are capable of actually measuring changes in daylength (Tauber *et al*., 1986). The widespread importance of photoperiodism in regulating diapause induction is reflected by the fact that it is used almost universally by insects in all geographic areas excluding areas within approximately

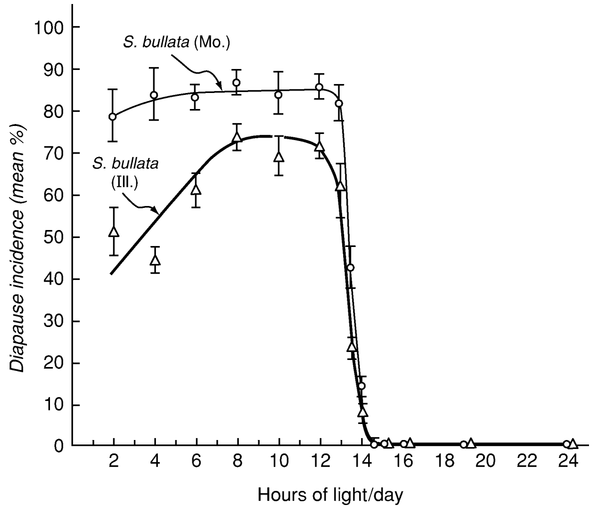

Figure 2 Critical photoperiod for diapause induction in populations of *Sarcophaga bullata* from Illinois (40° 15′ N) and Missouri (38° 30′ N) at 25 °C. (Reproduced with permission from Denlinger, D.L., **1972**. Induction and termination of pupal diapause in *Sarcophaga* (Diptera: Sarcophagidae). *Biol. Bull. Wood's Hole 142*, 11–24.)

5° of the equator. Diapause is still prevalent in the equatorial region, but other cues such as temperature, rainfall, or plant volatiles replace photoperiod as the cue for diapause induction in that region (Denlinger, 1986).

With a few exceptions, temperature also influences the decision to enter diapause. While it may act alone as the environmental cue used for diapause induction in some tropical species, more commonly it acts in concert with photoperiod. As shown in Figure 3a, low temperature commonly increases the diapause incidence observed at short daylength without influencing the critical photoperiod, but in some cases the critical photoperiod will shift toward longer daylengths at low temperature (Figure 3b). Under natural conditions, insects are simultaneously subjected to thermoperiods as well as photoperiods. In a number of cases, thermoperiod can substitute for a

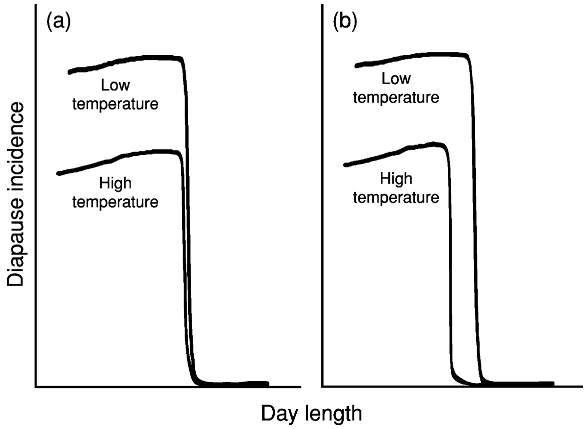

Figure 3 Low temperature can impact the photoperiodic response curve in two ways. (a) In some cases, the critical photoperiod remains the same but the incidence of diapause at short daylengths is higher. (b) In other instances, the critical photoperiod is also shifted toward longer daylengths at low temperature. (Reproduced with permission from Denlinger, D.L., **2001**. Interrupted development: the impact of temperature on insect diapause. In: Atkinson, D., Thorndyke, M. (Eds.), Environment and Animal Development: Genes, Life Histories and Plasticity. BIOS Scientific Publishers, Oxford, pp. 235–250.)

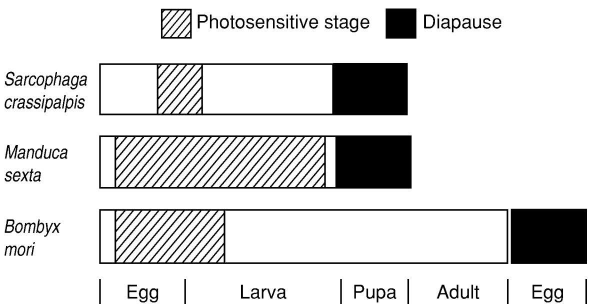

Figure 4 The relationship between the photosensitive stage and the stage of diapause in three insect examples. (Reproduced with permission from Denlinger, D.L., **1985**. Hormonal control of diapause. In: Kerkut, G.A., Gilbert, L.I. (Eds.), Comprehensive Insect Physiology, Biochemistry and Pharmacology, vol. 8. Pergamon Press, Oxford, pp. 353–412.)

photoperiodic signal, and it presumably does so by linkage to a common mechanism (van Houten and Veerman, 1990). Other factors that may contribute to the diapause decision include food presence (Fielding, 1990), food quality (Hare, 1983; Overmeer *et al.*, 1989), plant volatiles (Ctvrtecka and Zdarek, 1992), pheromones (Kipyatkov, 2001), and crowding (Desroches and Huignard, 1991; Saunders *et al.*, 1999).

The photosensitive stage, the stage that receives the photoperiodic cues used to program diapause, usually occurs fairly far in advance of the actual diapause stage, as noted in **Figure 4**. The photosensitive stage may be as brief as 4 days as observed in *Sarcophaga crassipalpis*, or it may encompass much of the prediapause period as noted in *Manduca sexta*. In the extreme example noted in the silkmoth *Bombyx mori*, the photosensitive period actually occurs in the previous generation. If diapause is to be programmed by daylength, it is imperative that the correct photoperiodic signals be received during this photosensitive period. At other times during development the length of the day is of no consequence for the programming of diapause.

Thus, insects that rely on short days to program their diapause need to extract two types of information: (1) was the day short? and (2) how many short days were received? Answering the first question requires a sophisticated clock that can measure daylength with precision, and answering the second question requires a counter capable of summing the number of short days that comprise the photosensitive period (Saunders, 2002).

3.12.2.1.2. Letting mother decide In a number of parasitic Hymenoptera, higher Diptera, and some Lepidoptera it is the mother that decides the diapause fate of her progeny. This arrangement may be particularly useful in cases where the mother has access to environmental cues not readily accessible to her progeny. Most of these cases involve the mother determining the diapause status of her recently deposited eggs. In these cases the embryos are often in an early stage of development and may not yet be equipped with the sophisticated neural systems required to receive and respond to photoperiodic cues. *Bombyx mori* is in this category, and since quite a bit is known about diapause in this species it will be discussed separately (see Section 3.12.3.1.1). In other cases, however, the mother influences the diapause fate of her progeny in their larval (e.g., *Nasonia vitripennis*) or pupal (e.g., *S. bullata*) stages. This clearly implies that the mother is not simply exerting some direct effect on her progeny as might be expected in an embryonic diapause, but she is initiating an effect that is expressed at a much later stage of development.

In spite of the intriguing nature of these maternal effects very little is known about the mechanisms that regulate these transgenerational effects. In the flesh fly *S. bullata* a critical message that influences the maternal effect is transferred from the brain of the female to her ovary sometime between pupariation and shortly after adult emergence (Rockey *et al.*, 1989). Gamma aminobutyric acid (GABA) and octopamine possibly are involved in the transfer of information from mother to progeny (Webb and Denlinger, 1998). Differential display of mRNA revealed a transcript unique to the ovaries of females

that express the maternal effect, but the function of the protein it encodes is still unknown (Denlinger, 1998). How the mother can influence the diapause fate of her offspring offers an intriguing, and still unanswered, problem in development.

3.12.2.2. The Brain as Photoreceptor and Programmable Center

The conspicuous visual centers, the compound eyes and ocelli, are not the photoreceptors commonly used for perception of photoperiodic information. Most species that have been examined rely on extraretinal reception of the light signal (Shimizu and Hasegawa, 1988; Saunders and Cymborowski, 1996; Numata *et al*., 1997). Blackening or ablating the compound eyes frequently has no impact on the insect's ability to respond to photoperiod. In some cases translucent cuticular windows or lightened portions of cuticle overlay portions of the brain, thus facilitating the transfer of light to the photoreceptors in the brain. In classic experiments with the giant silkmoth, *Antheraea pernyi*, Williams and Adkisson (1964) elegantly demonstrated that the brain is the direct recipient of the light signal. This species terminates pupal diapause in response to long daylength, and by using a divided photoperiod chamber that offered diapause-terminating conditions to one half of the body and diapause-maintaining conditions to the other half, they were able to demonstrate that diapause can be broken only when the portion of the body containing the brain is exposed to diapause-terminating conditions. This is true even when the brain is transplanted to the abdomen of the pupa. In yet another elegant demonstration of the brain's role in photoreception, Bowen *et al*. (1984) demonstrated that the brain of *M. sexta,* when exposed *in vitro* to short days, is capable of eliciting diapause when implanted into a debrained pupa. Likewise, larval brain–subesophageal ganglion complexes of *B. mori* can be photoperiodically programmed for diapause *in vitro* and elicit a diapause response when reimplanted into larvae (Hasegawa and Shimizu, 1987).

More recently, however, several cases have been reported in which the compound eyes do play a role. Females of the fly *Protophormia terraenovae* (Shiga and Numata, 1997), and the bugs *Plautia crossota stali* (Morita and Numata, 1999), *Graphosoma lineatum* (Nakamura and Hodkova, 1998), and *Poecilocoris lewisi* (Miyawaki *et al*., 2003) cannot distinguish between short days and long days after surgical removal of the compound eyes. Painting the compound eyes of the bug *Riptortus clavatus* with phosphorescent paint effectively extends the photoperiod, resulting in the termination of diapause (Numata and Hidaka, 1983). By contrast, painting the head region above the pars intercerebralis fails to terminate diapause, thus suggesting that the compound eyes are the dominant photoreceptors for this species. Not all of the ommatidia of the compound eye are involved in the photoperiodic response of *R. clavatus*. By selectively removing the ommatidia from various regions of the compound eyes, it is evident that only the ommatidia in the central region of the compound eye are involved in this response (Morita and Numata, 1997b). Evidence from circadian rhythms suggests that in some cases, e.g., *Protophormia terraenovae*, both retinal and extraretinal pathways contribute to rhythm entrainment (Hamasaka *et al*., 2001). Such may also prove to be the case for photoperiodism in some species.

The diapause program resides within the brain, and can be transferred from one individual to another by transplantation of the programmed brain, as demonstrated in the embryonic diapause of *B. mori* (Hasegawa and Shimizu, 1987), pupal diapause of *M. sexta* (Safranek and Williams, 1980; Bowen *et al*., 1984) and *S. crassipalpis* (Giebultowicz and Denlinger, 1986), and adult diapause of the linden bug, *Pyrrhocoris apterus* (Hodkova, 1992). In *M. sexta* the duration of diapause is also programmed within the brain prior to the onset of diapause. In this species, the number of short days the larva receives determines the length of the pupal diapause. Short days throughout produce a high incidence of diapause but such a diapause is of short duration. By contrast, exposure to only a few short days yields a low incidence of diapause, but a diapause of long duration. Brain transplantation experiments show that information about the duration of the diapause can be transplanted along with the brain (Denlinger and Bradfield, 1981).

Precisely which cells within the brain are involved in photoreception and storage of diapause information remains unknown in most cases, but future studies pinpointing photoreceptor pigments and specific clock genes involved in photoperiodism should reveal the correct target sites for this critical information. In the vetch aphid, *Megoura viciae*, antibodies directed against invertebrate and vertebrate opsins and phototransduction proteins consistently label an anterior ventral neuropile region of the protocerebrum (Gao *et al*., 1999). Identification of this region is consistent with previous experiments using localized illumination and microlesions to identify the photoreceptor region.

3.12.2.3. Transduction of the Environmental Signals

When photoperiod is the primary cue leading to the induction of diapause, several key molecular components are essential. The first key component is a photoreceptor capable of distinguishing between the photophase and scotophase. Secondly, the insect must have the capacity to measure the length of each photophase (or scotophase), and thirdly, the insect must be able to sum the number of short (or long) days it has seen. Although our understanding of the molecular events involved in the transduction of the environmental signals remains in its infancy, several recent studies have proven insightful, and in addition the early literature offers valuable clues about the processes involved. As discussed above, the photoreceptive organ, and in some cases candidate cells, have been identified for several diapause models. Action spectra that elicit diapause have been described for several species, and in most cases the blue–green range of the visual spectrum is most sensitive to diapause induction (Truman, 1976), thus indicating that any putative photoreceptor involved in the diapause response must have features consistent with these early observations.

How temperature exerts its effect on the diapause response is poorly understood. One attractive model proposed by Saunders (1971) for flesh flies suggests that low temperature simply increases the number of short days the larvae receive: in this system, 14 short days are required for diapause induction, and lowering the temperature retards development and hence a larger portion of the population experiences the required number of short days. While this model is attractive for species with a long photosensitive period, such a system seem less likely to operate in other insects, including some closely related flesh fly species, that have a very short photosensitive period. In some cases, thermoperiod can completely substitute for photoperiod as an environmental cue. Adult diapause is induced in the predatory mite *Amblyseius potentillae* by a short day photoperiod or by rearing under constant darkness with a thermoperiod of 16 h at 15 °C and 8 h at 27 °C (van Houten *et al.*, 1987). Exposing *A. potentillae* to short day photoperiods or to short day thermoperiods either concurrently or in succession is successful for inducing diapause, thus suggesting that a single physiological mechanism is integrating photoperiodic and thermoperiodic information to regulate diapause (van Houten and Veerman, 1990). The argument that a single mechanism is involved is further strengthened by the observation that mites reared on a diet deficient in carotenoids/vitamin A (see Section 3.12.3.2.1) lose their ability to respond to either photoperiod or thermoperiod (van Houten *et al.*, 1987). By contrast, carotenoids/vitamin A are essential for the photoperiod response but not for the thermoperiodic response in the cabbage butterfly, *Pieris brassicae* (Claret, 1989). Clearly, species differences must again be evident in the integration of photoperiodic and thermoperiodic information.

3.12.2.3.1. Cryptochromes and opsins One of the most important quests in diapause research is to identify the photoreceptor pigment involved in this response. While a number of candidate proteins have been identified, most appear to be involved in visual perception. Only a few are candidates for involvement in photoperiodism, especially given the blue light sensitivity of the diapause response and the common involvement of extraocular light reception. One such candidate is the flavin-based blue light photoreceptor cryptochrome (CRY). This protein has been directly linked to the circadian pacemaker of the fruit fly *Drosophila*, acting to daily reset the clock upon initiation of the photophase as detailed below. Null mutants of CRY exhibit poor synchronization during light cycling, while rhythmicity is present in constant darkness (Stanewsky *et al.*, 1998), features that support a role for CRY in entrainment of the circadian clock by photoperiod. The possible role of CRY in diapause induction has yet to be established, although *cry* expression is upregulated in adult *S. crassipalpis* when the flies are reared at short as opposed to long daylengths (Goto and Denlinger, 2002b).

Another group of proteins that have been linked to photoperiodism are the carotenoid/vitamin A-associated opsin photoreceptors. A causal link with diapause has been established by rearing insects on carotenoid-free diets. Although several species, including *D. melanogaster* (Zimmerman and Goldsmith, 1971) and *B. mori* (Shimizu *et al.*, 1981), retain circadian behavioral patterns when reared on a carotenoid-free diet, the induction of diapause can be affected in a number of species, including adults of the predatory mite *A. potentilla* (van Zon *et al.*, 1981; Veerman *et al.*, 1985) and spider mite *Tetranychus urticae* (Bosse and Veerman, 1996), embryonic diapause of *B. mori* (Shimizu and Kato, 1984), and pupal diapause of *Pieris brassicae* (Claret, 1989; Claret and Volkoff, 1992). The opsin proteins have been linked to photoperiodism as well. Melanopsin has been implicated in circadian mechanisms in vertebrates. In mice, null mutants of melanopsin retain circadian rhythmicity in constant darkness, but lack photoperiodic entrainment

(Panda *et al*., 2002; Ruby *et al*., 2002). Similar work has yet to be conducted in insects, although boceropsin, which shows central nervous system (CNS)-specific expression, has been cloned from *B. mori* (Shimizu *et al*., 2001). A comparison of the phenotypes of null mutants of opsin-deficient and carotenoid-deficient silkworms will be be insightful.

3.12.2.3.2. Clock genes Regardless of the type of photoreceptor involved in diapause, the photoreceptor must be functionally connected to a timekeeping mechanism to exert its effect. The molecular basis of timekeeping is particularly well described in *D. melanogaster* (Schotland and Sehgal, 2001), although other species are beginning to be characterized as well (see **Chapter 4.11**). In *Drosophila*, the clock is composed of a multiple component autoregulatory feedback loop (reviews: Reppert and Weaver, 2000; Williams and Sehgal, 2001; Stanewsky, 2002). The best-described components involve the interactive oscillations of the proteins period (PER), timeless (TIM), clock (CLK), and cycle (CYC). In this system, the proteins PER and TIM heterodimerize to enter the nucleus and transcriptionally repress the expression of CLK and CYC. Conversely, CLK and CYC act to transcriptionally upregulate both PER and TIM. Thus, when levels of the proteins PER and TIM are high, they repress the transcription of CLK and CYC. As levels of CLK and CYC diminish, transcription of PER and TIM are decreased, until they are low enough that they no longer repress CLK and CYC. Once the levels of CLK and CYC are restored, PER and TIM will again be transcribed. The genes in this autoregulatory loop, in addition to several others including *vrille, doubletime*, and *CREB2*, create two interacting phases of protein oscillations (PER with TIM and CLK with CYC) thus creating a circadian rhythm of gene expression. The connection of this circadian pacemaker to photoperiod is attained through the interaction of the proteins TIM and CRY. TIM is degraded in the photophase through the action of CRY, thereby "resetting the clock" according to the daily light cycle. Although most of these genes appear to be conserved, it is evident that details of the clock mechanism may differ among species. For example, in *Antheraea pernyi,* PER apparently does not enter the nucleus (Sauman and Reppert, 1996).

These major clock genes have thus far been studied intensely in association with circadian rhythms, yet it is not absolutely clear whether diapause has a circadian basis. Although much evidence points to a role of circadian rhythms in the programming of diapause (Saunders, 2002), several arguments defend the position that diapause does not have a circadian basis (Veerman, 2001; Veerman and Veenendaal, 2003). Even if diapause does have a circadian basis it is not clear whether the same clock genes and response mechanisms are involved in both circadian rhythmicity and photoperiodism (diapause). In fact, several experiments suggest two distinct mechanisms. In both spider mites (Veerman and Veenendaal, 2003) and the blowfly *Calliphora vicina* (Saunders and Cymborowski, 2003), it is possible to segregate the photoperiodic response mechanism from the mechanism governing daily behavioral rhythms. Experiments utilizing mutants suggest that distinct mechanisms may operate in these two systems. *per* null mutants of *D. melanogaster* are arrhythmic, yet they retain the ability to enter adult diapause (Saunders *et al*., 1989; Saunders, 1990). Similarly, in the drosophilid *Chymomyza costata,* mutants with reduced rhythmicity continue to enter larval diapause (Lankinen and Riihimaa, 1992), and *per* null mutants retain the capacity for diapause as well (Shimada, 1999; Kostal and Shimada, 2001). It is, of course, possible that there is enough redundancy in the system so that knocking out a single gene does not render the timekeeping mechanism involved in photoperiodism inoperative. In *S. crassipalpis, period, cycle, clock,* and *cryptochrome* show little differences in expression patterns when the flies are reared under short day or long day. However, the expression of *timeless* is greatly suppressed in long days as compared to short days (Goto and Denlinger, 2002b). *tim* thus emerges as a potential player in the mechanism distinguishing short and long days.

Though we can not yet be certain which clock-related genes are involved in programming diapause, there are already sufficient experiments in the literature suggesting that the gene interplay described so elegantly for the control of circadian rhythms of behavior in *D. melanogaster* may not be fully relevant to diapause induction. Resolution of these disparities is pivotal for understanding diapause induction at the molecular level.

3.12.2.4. Storage Proteins

The approach to diapause is frequently accompanied by the accumulation of high concentrations of hemolymph storage proteins that persist throughout diapause. This feature of diapause, first noted in larvae of the southwestern corn borer, *Diatraea grandiosella* (Brown and Chippendale, 1978), has been frequently observed in larvae, pupae, and adults destined for diapause. Although such proteins are sometimes referred to as diapause-associated proteins, they are not truly unique to diapause and

instead can be included in the broad category of storage proteins. These same proteins are also present in nondiapausing individuals. What is unique to diapause is the long time interval over which they persist, and in some cases the concentrations in the hemolymph during diapause are much higher than ever observed in nondiapausing individuals.

In nondiapausing individuals, such proteins are abundant during metamorphosis. At this time insects endure periods of nonfeeding as they transit from one developmental stage to the next. This period of nonfeeding and high energy demand is particularly acute in holometabolous insects as they go through the larval to pupal to adult transformation. To help meet this need for metabolic reserves, feeding larvae synthesize storage proteins in the fat body and secrete them into the hemolymph where their titers reach extraordinary levels just prior to pupation. Most of the storage proteins are reabsorbed into the fat body and stored in granules at the time of the pupal molt. The granules are broken down and the amino acids are used for synthesizing the proteins needed to construct adult tissues. Insect storage proteins form a diverse group of proteins, differing significantly in amino acid composition and ranging in size from the high molecular weight hexameric proteins (200–500 kDa) to 35 kDa. Several excellent reviews discuss insect storage proteins (Telfer and Kunkel, 1991; Haunerland, 1996; Burmester *et al*., 1998). Here the focus is only on those aspects of storage proteins that directly relate to diapause.

For insects that diapause in the larval stage, the high weight hemolymph proteins can be divided into two classes based on their relationship to diapause. Proteins in the first class are present in both diapausing and nondiapausing individuals; e.g., *D. grandiosella* (Lenz *et al*., 1987), the pink bollworm, *Pectinophora gossypiella* (Salama and Miller, 1992), the spruce budworm, *Choristoneura fumiferana* (Palli *et al*., 1998), the stem-borer *Busseola fusca* (Osir *et al*., 1989), and the wax moth *Galleria mellonella* (Godlewski *et al*., 2001). The second class includes hemolymph proteins whose expression is restricted to, or greatly enhanced in, diapause-programmed individuals, e.g., the codling moth, *Cydia pomonella* (Brown, 1980), *D. grandiosella* (Dillwith and Chippendale, 1984; Lenz *et al*., 1987), *B. fusca* (Osir *et al*., 1989), *P. gossypiella* (Salama and Miller, 1992). One species may synthesize one or both of these classes of proteins. In insects that diapause as adults, two peaks of storage protein synthesis commonly occur during development, one in later instars and the other in diapausing adults. The cycle of storage protein synthesis is best exemplified by the Colorado potato beetle, *Leptinotarsa decemlineata* and *R. clavatus*. In *L. decemlineata* diapause protein 1 (DP-1) is first detected on day 2 of the fourth larval instar (de Kort and Koopmanschap, 1994). The DP-1 titer continues to increase throughout the fourth instar then decreases once the larvae starts digging, as they seek a pupation site. Trace levels of DP-1 transcript are detectable in newly emerged diapause-programmed adults. DP-1 expression increases again 2 days after emergence and is still detectable 2 months into diapause. A somewhat more complicated storage protein expression pattern occurs in *R. clavatus* (Chinzei *et al*., 1991), which synthesizes four cyanoproteins, CP-1 to CP-4. CP-4 is expressed cyclically in the first to fourth nymphal instars, with maximum expression occurring in the middle of each instar. During the final instar all four CPs are expressed. All four CPs are present in newly emerged nondiapausing adults but quickly disappear by day 2. CP-1 is again expressed on day 4 and deposited into the developing ovaries. In diapause-programmed bugs all four CPs are expressed beginning around day 4 post-emergence and continuing through to at least 70 days (Chinzei *et al*., 1992). One of the most interesting aspects of storage protein physiology is their continuous expression in some species during diapause, e.g., *P. gossypiella* (Salama and Miller, 1992), *L. decemlineata* (de Kort and Koopmanschap, 1994), *Choristoneura fumiferana* (Palli *et al*., 1998), and *G. mellonella* (Godlewski *et al*., 2001). It is not at all clear why a diapausing insect would invest scarce metabolic reserves in the synthesis of a storage protein. This pattern of continuous synthesis may suggest some alternative use for such proteins during diapause.

Although the fat body is the primary site of synthesis of storage proteins, other tissues have also been shown to synthesize these proteins, e.g., the midgut, epidermis, and pericardial cells of the lepidopteran *Calpodes ethlius* (Palli and Locke, 1987) and testis of the tobacco budworm, *Heliothis virescens* (Miller *et al*., 1990). Within the testis of *H. virescens* two storage proteins (p82 and 76) are synthesized by the sheath and exported only into the testis lumen. The testis cyst cells actively import p82 which is then deposited into the sperm mitochondria (Miller *et al*., 1990). Exposing *H. virescens* larvae to elevated temperature induces a summer diapause characterized by arrested sperm development (Henneberry and Butler, 1986). Larvae and pupae exposed to high temperature synthesize significantly more p82 than control males. Within 7 days after returning heat-treated pupae to the normal rearing temperature, p82 synthesis rate decreases to levels comparable to that of the control males. In response to heat treatment p82 is transported into

the spermatocytes' nuclei instead of the mitochondria as noted in control males. Seo and Kim (1992) speculate that p82 may function in arresting sperm development.

Juvenile hormones and ecdysteroids are both known to regulate storage proteins. Treating diapausing females of *R. clavatus* with the juvenile hormone (JH) analog methoprene induces a shift from the diapause expression pattern to the nondiapause pattern. Methoprene treatment inhibits synthesis of CP-4 (the principal diapause CP), and increases synthesis of CP-1 (the principal nondiapause CP) and vitellogenin (Miura *et al.*, 1991). Treating day 1 short-day *L. decemlineata* with the JH analog pyriproxyfen shifts the initiation of DP-1 synthesis from day 2 to day 15 and induces synthesis of the vitellogenin subunits (de Kort *et al.*, 1997). Treating the last larval instar of *G. mellonella* with 20-hydroxyecdysone (20E) inhibits synthesis of the storage proteins Lhp76 and 82 (Ray *et al.*, 1987). Abdomens deprived of ecdysteroids by ligating the larvae behind the prothoracic segment synthesize both Lhp76 and 82 for at least 15 days postligation. Lhp76 and 82 exhibit differential sensitivity to 20E regulation, with Lph 72 being significantly more responsive to 20E than Lhp82 (Ray *et al.*, 1987). *Manduca sexta* has two distinct members of the methionine-rich storage protein family (SP1A and SP1B) that are differentially regulated by 20E and JH (Corpuz *et al.*, 1991). Ligating fifth instar larvae of *M. sexta* between the first and second abdominal segments inhibits the expression of both SP1A and SP1B. Expression of SP1A and SP1B can recover in these ligated larvae in response to injection of 20E. 20E induces twice the level of expression of SP1B than of SP1A, demonstrating a clear difference in sensitivity to 20E induction. Topically applying the JH mimic fenoxycarb to day 2 and 3 fifth instar larvae inhibits expression of SP1A and SP1B. In summary, the regulation of storage proteins appears to be dictated by the overall regulatory contol of development, with JH and ecdysteroids as the major players. Thus, the unique patterns of storage protein synthesis and utilization observed during diapause are presumably directed by these key endocrine regulators as they preside over the diapause program.

3.12.3. Endocrine Regulators

3.12.3.1. Hormonal Basis for Embryonic Diapause

Embryonic diapauses are common among the Orthoptera, Hemiptera, Lepidoptera, and Diptera (especially species of *Aedes* mosquitoes), but there are reports from other orders as well. The diverse stages in which embryonic diapauses occur suggest a potentially rich diversity of regulatory schemes. Thus far, hormonal regulation has been examined only in a few species of Lepidoptera, and it is evident from the Lepidoptera that no single regulatory scheme prevails.

The most intensely studied embryonic diapause is that of *Bombyx mori*. Classic experiments, begun in the 1950s by Fukuda (1951, 1952) and Hasegawa (1952), firmly set the stage for a wealth of papers documenting the regulatory mechanism controlling the early embryonic diapause in this commercially important species. More recently, work from the Yamashita laboratory provided major contributions to the hormonal, biochemical, and molecular characterization of diapause in *B. mori*.

Diapause in *B. mori* differs from that of most model species. While both temperature and daylength are key components of the diapause decision, the specifics are reversed as compared to other diapause models. High temperature and long daylength prompt diapause induction, while low temperature and short daylength lead to nondiapause development. Diapause induction in this species is under strict maternal control. The photosensitive stage occurs far in advance of the actual diapause stage: exposure of developing female embryos and larvae to diapause-inducing conditions will cause the female to produce eggs that are destined to enter diapause. This effect is mediated by diapause hormone (DH), a neuropeptide released by the female adult during her period of egg maturation. DH acts upon the ovarioles, leading to the production of diapause-destined eggs, as described below. After being oviposited, the silkworm embryos enter a diapause characterized by a G_2 cell cycle arrest (Nakagaki *et al.*, 1991). Once diapause has been established, this cell cycle arrest can be broken only after the embryos have been chilled for 1–3 months at 5 °C. Following this mandatory chilling period, development can be initiated when the embryos are transferred to a higher temperature.

As early as 1926, ovary transplantation experiments indicated that the factor controlling diapause induction is bloodborne (Umeya, 1926). Later studies by Fukuda and Hasegawa identified the brain and subesophageal ganglion as the tissues controlling the release of the diapause-inducing factor now known as DH, and bioassays performed by injecting nondiapause-type individuals with tissue extracts showed DH activity in subesophageal ganglion and brain extracts.

3.12.3.1.1. Diapause hormone and its action in *Bombyx mori*

Although the activity of DH was established quite early, purification and sequencing of

the peptide progressed more slowly. An initial chemical characterization was made from extracts of 15 000 isolated brain–subesophageal ganglion complexes (Hasegawa, 1957). Further analysis, including an assessment of amino acid composition, was made from the extracts of 1 million isolated male adult heads (Isobe *et al.*, 1973). A final push for determining the amino acid sequence began in 1987, when extracts from 100 000 subesophageal ganglia yielded enough material for isolation and subsequent analysis. Amino acid sequencing finally yielded a 24 amino acid peptide (Imai *et al.*, 1991). Subsequent cloning of the cDNA for DH confirmed the amino acid sequence (**Figure 5**), and led to further characterization of the hormone (Sato *et al.*, 1992, 1993).

The amino acid sequence of DH indicates that it is a member of the FXPRL amide peptide family and shares the same five amino acid sequence at

TDMKDESDRGAHSERGALWFGPEL-NH_2

Figure 5 Amino acid sequence of diapause hormone from *Bombyx mori*.

the C-terminus with a variety of hormones including pheromone biosynthesis activating neuropeptide (PBAN) and pyrokinin. Although the sequence of PRL-NH_2 is the minimum structure required for DH activity (Imai *et al.*, 1998), substantially greater activity is noted from the C-terminal pentapeptide. By synthesizing a series of DH analogs of different lengths, it was determined that two other regions of the peptide in the center and near the N-terminus also contribute to biological activity (Saito *et al.*, 1994). The C-terminal amide group is essential for biological activity (Suwan *et al.*, 1994).

Cloning of the cDNA for DH resulted in a 800 bp nucleic acid sequence with a 192 amino acid open reading frame, a size much larger than the 24 amino acid DH peptide (Sato *et al.*, 1992, 1993). Computer analysis of the deduced amino acid sequence reveals that not only DH, but several additional neuropeptides, including PBAN and three other members (subesophageal ganglion neuropeptides) of the FXPRL family of neuropeptides are encoded in the single open reading frame (**Figure 6**).

Figure 6 The cDNA sequence and deduced amino acid sequences of diapause hormone–pheromone biosynthesis activating neuropeptide (DH-PBAN) from *Bombyx mori*, showing the sequences and locations of DH, PBAN, and other putative hormones within the preprotein. (Adapted from Sato, Y., Oguchi, M., Menjo, N., Imai, K., Saito, H., *et al.*, **1993**. Precursor polyprotein for multiple neuropeptides secreted from the subesophageal ganglion of the silkworm *Bombyx mori*: characterization of the DNA-encoding diapause hormone precursor and identification of additional peptides. *Proc. Natl Acad. Sci. USA 90*, 3251–3255.)

The resulting polyprotein is a prohormone that is post-translationally processed to excise the active peptides. The presence of PBAN and other neuropeptides in the DH prohormone stresses the importance of posttranslational control of hormone release. This also helps to explain the formerly perplexing data indicating the presence of DH activity from a wide variety of developmental stages, from both sexes, and from both diapausing and nondiapausing individuals. It is now assumed that the large peak of activity seen in developing pharate adults (Sonobe *et al.*, 1977) can be attributed not to a function of DH, but to the synthesis of PBAN as the moth completes its maturation and prepares for the synthesis of pheromones.

Genomic characterization of DH has also been achieved: Southern blotting reveals a single copy of DH-PBAN in the *Bombyx* genome, and linkage analysis suggests that it is located on chromosome 11 (Pinyarat *et al.*, 1995). The gene contains six exons separating five introns; the sequence encoding DH is located in the first two exons. The region upstream of the open reading frame includes an ecdysone response element and five homeodomain TAAT binding core domains (Xu *et al.*, 1995a).

Even in the absence of purified hormone or the DH clone, early researchers were able to characterize the DH control mechanism, as well as the site of DH synthesis and release. Early transplantation experiments indicated high DH activity in the subesophageal ganglion, and histological studies from Fukuda's laboratory identified a single pair of cells in the subesophageal ganglion as the likely site of DH release. More sensitive molecular methods have largely confirmed these results. Using real-time polymerase chain reaction (RT-PCR), it has been determined that DH is exclusively expressed in the subesophageal ganglion; no DH expression is observed in the brains, or in thoracic or abdominal ganglia, or in nonneural tissues (Sato *et al.*, 1994). *In situ* hybridization has been used to further detail the expression of DH within the subesophageal ganglion. Expression is concentrated in 12 cells grouped into three clusters along the midline of the subesophageal ganglion (Sato *et al.*, 1994). Surgical manipulation indicates that the different clusters are responsible for different activities of the prohormone. Females retaining only the two cells in the posterior cluster continue to be capable of inducing diapause in their progeny, while females with only the six cells in the medial cluster retain PBAN function. Surgical removal of the anterior cluster of four cells does not substantially affect either function, indicating that this cluster may be involved in the function of other portions of the prohormone

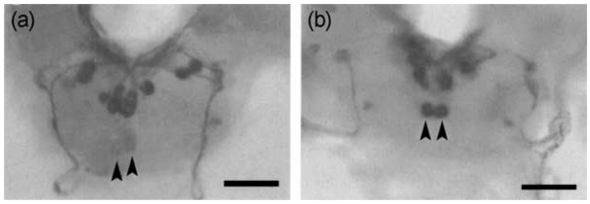

Figure 7 Localization of neurosecretory cells containing diapause hormone (DH) within the subesophageal ganglion of (a) diapause and (b) nondiapause type adults of *Bombyx mori*. Release of DH leads to a decrease of staining in diapause type individuals. Arrows indicate the somata containing DH. (Adapted from Sato, Y., Shiomi, K., Saito, H., Imai, K., Yamashita, O., **1998**. (Ichikawa *et al.*, 1996). Further supporting evidence for the identity of the DH cells comes from an immunohistochemical study using antibodies recognizing the FXPRL amide. This antibody recognizes several cells in the brain–subesophageal ganglion complex that contain peptides in this family. Of the 12 cells in the subesophageal ganglion that exhibit antigenicity, two show decreased staining in diapause-type as compared to nondiapause-type individuals (**Figure 7**), indicating release of the peptide in diapause-type females (Sato *et al.*, 1998). Immunocytochemistry combined with intracellular Lucifer Yellow injections reveals that the axons of cells in all three clusters pass through the brain and into the corpus cardiacum (Ichikawa *et al.*, 1995), the known site of DH release.

While previous studies showed DH activity in larval, pupal, and adult stages (Hasegawa, 1964), further resolution of DH expression patterns was not possible until more sensitive molecular techniques were implemented. Using RT-PCR, it was determined that the transcription of DH-PBAN is under the control of both development and temperature (Xu *et al.*, 1995b; Morita *et al.*, 2004). When *B. mori* is raised under diapause-inducing conditions of 25 °C, five peaks of synthesis are noted throughout development: the first peak occurs during embryogenesis, one peak during both the fourth and fifth instars, and two peaks during pupal and adult development. By contrast, when the insects are rearing under a nondiapausing-temperature of 15 °C, only the final peak of gene expression during pupal–adult development is observed (**Figure 8**). This final peak of transcription is most likely associated with PBAN, rather than DH, activity.

Several studies offer insights into the neural control of DH expression and release. Both *in vivo* and *in vitro* studies have shown that translation of the gene encoding DH is under control of the

neurotransmitter dopamine. Dopamine levels in both the hemolymph and brain–subesophageal ganglion complexes of diapause-type individuals is significantly higher than in nondiapause-type individuals during the late larval and early pupal stages (Noguchi and Hayakawa, 2001). The high dopamine levels correlate with an increase in dopamine decarboxylase expression. Interestingly, a specific subset of cells appears to be responsible for the elevated dopamine titer. A critical role for dopamine associated with DH activity is further suggested by experiments in which DOPA is fed to nondiapause-type larvae during the final larval instar or injected into nondiapause-type pupae. Both of these treatments can elicit the production of diapausing eggs by nondiapause-type females. Additionally, pupal injections elevate DH mRNA in the brain–subesophageal ganglion complexes. *In vitro* studies further confirm the effects of dopamine. DH mRNA levels in isolated brain–subesophageal ganglion complexes from nondiapause-type pupae are elevated within 2 h after addition of either DOPA or dopamine to the medium.

Neuronal effects on DH are not restricted to transcriptional control. The release of DH from the subesophageal ganglion is under control of GABAergic neurons. Culturing isolated brain–subesophageal complexes from diapause-egg producing females in the presence of the inhibitory neurotransmitter GABA causes a substantial reduction in the release of DH , while incubation with picrotoxin, the GABA inhibitor, promotes DH release from the cultured brain–subesophageal complexes (Hasegawa and Shimizu, 1990; Shimizu *et al*., 1997). Further insight into the control of DH release may be gleaned from data for PBAN, which shares a common proprotein with DH. PBAN release is under circadian control, and under a light–dark cycle, PBAN-releasing neurons fire during the scotophase. This firing pattern persists with a periodicity of ~24 h (free runs) even in constant darkness, thus indicating the circadian nature of this firing pattern (Tawata and Ichikawa, 2001). At this point, however, there is no direct evidence indicating a circadian pattern of DH release.

The ovary appears to be the sole target for DH. Its action is most certainly mediated through a second messenger system, although specifics of the signal transduction system remain unclear. *In vitro* experiments suggest that early events, such as the upregulation of trehalase described below, are regulated by Ca^{2+} ion influx. Addition of the chelating agent egtazic acid (EGTA) to the incubation medium suppresses DH activity on trehalase, while the addition of Ca^{2+} restores this activity (Ikeda *et al*., 1993). Later events may also involve cyclic nucleotide cascades. DH acts to reduce the concentration of cyclic GMP in diapause-destined eggs through the regulation of guanylate cyclase activity (Chen *et al*., 1988; Chen and Yamashita, 1989).

A key indicator of DH activity reported in the older literature is a metabolic switch, resulting in the accumulation of glycogen in diapause-destined eggs. This accumulation is a result of the activity of the enzyme trehalase, which exhibits transcriptional upregulation after DH injection (Su *et al*., 1994). Accumulated glycogen is then converted to sorbitol, which acts as a classic antifreeze to lower the supercooling point of the diapausing eggs (Chino, 1957, 1958). Upon diapause termination, sorbitol is reverted to glycogen, which is subsequently used as an energy reserve. Recent data revealed the important observation that sorbitol accumulation plays a regulatory role as well (Horie *et al*., 2000). When diapause-destined eggs are dechorionated and cultured in Grace's medium, diapause is averted. When sorbitol is added to the medium the ability to diapause is restored in a dose-dependent fashion. Substantial inhibition of development is noted at biologically relevant concentrations of sorbitol. Trehalose elicits similar inhibitory effects, while glycerol is less effective. A regulatory role for sorbitol is further supported by data showing that subsequent removal of sorbitol induces resumption

of development, and that nondiapause-destined eggs arrest development when incubated in sorbitol.

3.12.3.1.2. Other schemes for regulating embryonic diapause There is no evidence to suggest that the regulatory scheme carefully documented in *B. mori* is relevant to other forms of embryonic diapause. Unfortunately other species have not received nearly the attention devoted to the silkworm, but the fragments of information that are available indicate a potentially rich diversity of regulatory mechanisms operating to halt development in embryos. Embryonic diapauses are enormously diverse, as indicated by the wide range of stages at which development is arrested, and the challenge of working on embryos has limited the number of researchers willing to address this difficult stage. Thus far, three distinct regulatory schemes have been suggested for embryonic diapause as alternatives to the scheme noted in *B. mori*.

The gypsy moth, *Lymantria dispar,* diapauses as a pharate first instar larva. Several lines of evidence indicate that this diapause is induced and maintained by an elevated ecdysteroid titer. Using synthesis of a 55 kDa gut protein, now known to be hemolin (Lee *et al.*, 2002), as an indicator of diapause, Lee and Denlinger (1997) demonstrated that placing a ligature behind the prothoracic gland blocks hemolin synthesis, and coculturing the gut with an active prothoracic gland promotes hemolin synthesis by the gut. Synthesis of this diapause indicator protein, hemolin, can also be induced if an isolated abdomen is injected with 20E or an ecdysteroid agonist RH-5992. KK-42, an imidazole derivative thought to block ecdysteroid synthesis, averts diapause in this species (Suzuki *et al.*, 1993; Bell, 1996; Lee and Denlinger, 1996), but this effect can be reversed with the application of ecdysteroids (Lee and Denlinger, 1997). And, at the end of the mandatory chilling period, diapause can be readily terminated if pharate larvae are transferred to high temperatures, but such individuals exposed to ecdysteroids fail to break diapause. Collectively, these results suggest that ecdysteroids are essential for diapause induction and maintenance. Experiments with a mutant, nondiapausing strain of *L. dispar* are also consistent with this idea (Lee *et al.*, 1997): all of the characteristics of the nondiapause strain could be switched to characteristics of the diapause strain by artificially subjecting pharate larvae from the mutant strain to elevated concentrations of ecdysteroid. Although ecdysteroids of maternal origin are well known to be incorporated into eggs, at this late stage of embryonic development the ecdysteroids are likely to be synthesized by the pharate larva's prothoracic gland. In the wild-type strain, the prothoracic gland appears to synthesize ecdysteroids continuously throughout diapause, and then shut down synthesis to terminate diapause. A diapause-promoting effect for ecdysteroids at first may seem paradoxical, especially considering the fact that a lack of ecdysteroids is the dominant feature of most larval and pupal diapauses (see Section 3.12.3.3.2). Yet, it is well known that a drop in the ecdysteroid titer is an essential signal permitting the ongoing progression of development in other systems (Slama, 1980), and the gypsy moth appears to have exploited this feature to bring about a halt to development.

The opposite effect can also be elicited by ecdysteroids, as reported for the embryonic diapauses of two locust species: the Australian plague locust *Chortoicetes terminifera* (Gregg *et al.*, 1987) and the migratory locust, *Locusta migratoria* (Tawfik *et al.*, 2002b). In both of these cases, nondiapausing eggs contain approximately three times the amount of ecdysteroids as found in diapausing eggs. In these species the diapauses occur early in embryonic development, and the ecdysteroids present are likely to be exclusively of maternal origin. In nondiapause eggs and those in which diapause was averted by high temperature, ecdysteroid titers increase after the stage at which diapause normally occurs (Gregg *et al.*, 1987), and likewise after diapause is terminated, the ecdysteroid titers increase (Tawfik *et al.*, 2000b). Whether this elevation at diapause termination is the result of *de novo* synthesis or hydrolysis of conjugated ecdysteroids of maternal origin remains unkown.

The pharate first instar larval diapause of the silkmoth *Antheraea yamamai* represents yet another intriguing regulatory scenario (Suzuki *et al.*, 1990). These experimental conclusions rely on differences in the efficacy of the imidazole KK-42 to terminate diapause following exposure to different portions of the body. KK-42 is highly efficacious in terminating diapause when the pharate first instar larva is intact, and it also works well to terminate diapause in a headless body. But diapause persists in the head–thorax compartment, thus suggesting the presence of a repressive factor from the thorax. Isolated abdomens break diapause whether or not KK-42 is added. From these results, Suzuki *et al.* (1990) conclude the presence of a diapause-promoting factor produced in the mesothorax, and a development-promoting factor produced in the region of the second to fifth abdominal segments. During diapause the diapause-promoting factor prevails and development is halted. Although the identities of these factors remain unknown, the effects can not be mimicked by

any of the obvious candidates: prothoracicotropic hormone, ecdysteroids, or JH.

3.12.3.1.3. Associated changes in gene expression In *B. mori,* expression patterns of several genes associated with the G_2 cell cycle arrest have been monitored. Flow cytometery indicates that 98% of the embryonic cells are in the G_2 phase 3.5 days after oviposition. Conversely, within 24 h after the artificial termination of diapause, up to 50% of the cells are in S phase (Nakagaki *et al*., 1991). Considerable interest has focused on the molecular basis of this cell cycle arrest, especially the genes that encode cyclin B and cyclin dependent kinase 2 (cdc2), the two genes most likely involved in mediating this arrest. Northern blotting and RT-PCR have demonstrated that levels of cyclin B drop substantially in both diapausing and nondiapausing eggs within two days after oviposition. Interestingly, incubating diapausing eggs at 5 °C to initiate diapause termination leads to a partial restoration of cyclin B levels, yet artificial termination of diapause has little effect on cyclin B mRNA levels. Together, these data suggest that there is not necessarily a connection between cyclin B transcription and mitotic activity (Takahashi *et al*., 1996). Analysis of *Bombyx cdc2* and *Bombyx cdc-2 related kinase* (*Bcdrk*) expression proved more promising: mRNA levels for both genes is substantially lower in diapausing individuals than in nondiapausing ones. Exposure to 5 °C boosts expression, as does artificial diapause termination (Takahashi *et al*., 1998). Together, these results suggest that *cdc2*, and perhaps *Bcdrk* are involved in the regulation of this G_2 cell cycle arrest during diapause.

Several other genes of interest to silkmoth diapause have also been characterized. Differential display was used to isolate a diapause upregulated gene, *BmEts* (Suzuki *et al*., 1999). This gene is highly upregulated in early diapause, but mRNA levels diminish to trace amounts after 50 days. Interestingly, in the nondiapause egg mutant *pnd*, *BmEts* expression is suppressed, indicating that *BmEts* expression is downstream of the *pnd* mutation. This information is especially intriguing because, as the name suggests, *BmEts* belongs to the *ETS* gene family of transcription factors which includes several genes such as *Drosophila E74*, a gene known to be important in the cell's response to ecdysone.

Differential display has also been used to investigate the molecular events occurring during the period of chilling required for diapause termination. These experiments resulted in the cloning of *Samui*, a novel gene containing a BAG domain (Moribe *et al*., 2001). This gene is inducible by low temperatures in nondiapausing individuals, but the response is much more pronounced in diapausing individuals. Upregulation persists for 30 days at low temperatures, and the gene is quickly downregulated when the eggs are returned to a higher temperature. Although the function of *Samui* during chilling remains unclear, it may be involved in protection against chilling injury. Similar to other genes of the BAG family, *Samui* can bind Hsp70, which suggests that it may affect low temperature survival. *Samui* may also be involved in the signal cascade of diapause termination. Downregulation of *Samui* occurs concurrently with the upregulation of sorbitol dehydrogenase, the enzyme involved in converting sorbitol to glycogen. As such it could be involved in removing the important sorbitol blockade to embryonic development, as noted earlier.

Beyond *Bombyx*, few species with an embryonic diapause have been examined for diapause-specific gene expression. Several mRNAs have been sequenced from the early embryonic diapause of *Aedes triseriatus,* but most encode unknown proteins and those that have been cloned do not appear to be specific for diapause (Blitvich *et al*., 2001). In the pharate first instar diapause of *L. dispar,* two defense-related proteins are upregulated during diapause: a 70 kDa heat shock protein begins to be synthesized at the onset of chilling (Denlinger *et al*., 1992), and the gene encoding hemolin is highly upregulated for the first 100 days of diapause, the period encompassing the mandatory chilling period (Lee *et al*., 2002). One of the cytoplasmic actins in the brain is conspicuously downregulated during diapause (Lee *et al*., 1998), and its absence thus serves as a good biomarker for diapause.

3.12.3.2. Hormonal Basis for Larval and Pupal Diapauses

Larval diapauses are best known from the Lepidoptera, but there are good examples of larval (or nymphal) diapauses in other orders as well. Diapause in the last larval instar is reported most frequently, but some larvae diapause in earlier instars or as prepupae. Pupal diapause has been examined extensively in Lepidoptera and the higher Diptera, but appears to be rare in other taxa. It is indeed the true pupal stage that is usually involved in diapause, but occasional reports indicate a diapause late in pharate adult development. Larval and pupal diapauses share much in common. Central to both is a failure to progress to the next metamorphic stage. This suggests that one of the key endocrine events regulating such a diapause is likely to be a failure of the prothoracic gland to produce the ecdysteroids

needed to initiate the next molt. Invariably, this has proven to be a key element of larval and pupal diapauses. One might also predict a shutdown until the end of diapause in the production of prothoracicotropic hormone (PTTH), the hormone from the brain that stimulates the prothoracic gland to produce ecdysone (see **Chapter 3.2**). This may often be the case but not always. The other major metamorphic hormone, JH, may or may not play a role, depending on the species.

3.12.3.2.1. Role of the brain–prothoracic gland axis The older literature is replete with experiments showing that activation of the brain is essential for terminating diapause. Of special significance are the classic experiments by Carroll Williams demonstrating that the brain of the giant silkworm *Hyalophora cecropia*, when activated by chilling, is capable of terminating diapause when implanted into a brainless pupa (Williams, 1946, 1947, 1952). These experiments were critical not only for understanding the mechanism of diapause but also for deciphering the endocrine basis for insect metamorphosis. One can now be more specific and attribute these brain effects not to the whole brain, but to the production of PTTH by a pair of neurosecretory cells in the pars intercerebralis of each brain hemisphere (Agui *et al.*, 1979).

In the pupal diapause of *M. sexta* intracellular electrical recordings of the cells that produce PTTH show all the characteristics of silent cells: high voltage thresholds, low input resistance, and few spontaneous action potentials (Tomioka *et al.*, 1995). Electrical differences between the PTTH cells of diapausing and nondiapausing pupae are already evident within 1 day after pupation. As diapause progresses in chilled pupae, the cells gradually display more spontaneous action potentials, and more excitatory postsynaptic potentials are observed. In spite of the early curtailment of neurophysiological activity in the PTTH cells, there are no corresponding ultrastructural changes that would appear to reflect the electrical silencing of the cells in early diapause (Hartfelder *et al.*, 1994).

One common method for monitoring PTTH activity is to culture prothoracic glands *in vitro* and monitor ecdysone production when brains or brain extracts are added to the culture medium. When this has been done, low PTTH activity associated with larval and pupal diapause has been observed in some cases. In *Diatraea grandiosella,* a species that diapauses late in the final larval instar, PTTH activity is far lower in brains and brain extracts from diapause-destined larvae and diapausing larvae than in nondiapausing larvae (Yin *et al.*, 1985). Likewise, in the European corn borer, *Ostrinia nubilalis*, PTTH activity is lower in brains of diapausing larvae than in nondiapausing brains (Gelman *et al.*, 1992). Similar low levels of PTTH activity are noted in the pupal diapause of the cabbage armyworm, *Mamestra brassicae* (Endo *et al.*, 1997). Yet, the brains from all of these species clearly show some PTTH activity, and pupal brain extracts from *M. sexta* (Bowen *et al.*, 1984) and *S. argyrostoma* (Richard and Saunders, 1987) actually have as much or more PTTH activity than brain extracts from nondiapausing pupae. Likewise, PTTH activity is higher in larvae of *S. peregrina* that are destined for pupal diapause than in larvae not destined for diapause (Moribayashi *et al.*, 1992). These observations suggest that the hormone may be present during diapause but is simply not released.

In *Heliothis virescens,* expression of the transcript that encodes PTTH persists at relatively high levels throughout larval development, but at the onset of wandering behavior, expression in larvae programmed for pupal diapause drops and remains low during diapause, while the transcript continues to be highly expressed in nondiapause-destined larvae and nondiapausing pupae (Xu and Denlinger, 2003). These observations suggest that, in this species, PTTH is regulated at the level of transcription. This conclusion is not easily reconciled with the above observations suggesting that PTTH is made but not released during diapause, but it is quite likely that considerable species variation may occur. Both a halt in PTTH synthesis or a failure of PTTH release could result in a developmental shutdown.

Several recent experiments suggest that high dopamine levels in the brain may be critical for diapause induction, possibly by preventing the release of PTTH. High levels of dopamine in the brains of diapause-destined larvae of *Chymomyza costata* (Kostal *et al.*, 1998), diapause-destined pupae of *M. brassicae* (Noguchi and Hayakawa, 1997), and pupae of *Pieris brassicae* (Puiroux *et al.*, 1990) suggest a causal relationship. In diapausing pupae of *Antheraea pernyi*, a drop in brain dopamine is noted shortly before the surge of ecdysteroids that elicits diapause termination (Matsumoto and Takeda, 2002). But the most compelling evidence suggesting a role for dopamine is the fascinating observation that feeding L-DOPA to last instar larvae of *M. brassicae* reared under long daylengths (not diapause-inducing) elicits a diapause-like state in the pupae (Noguchi and Hayakawa, 1997). Other than DH in *Bombyx*, there are a few examples of chemical agents capable of inducing diapause or a diapause-like state, thus this result with DOPA feeding is quite striking. A potential role is also discussed for dopamine in the induction of embryonic diapause of

B. mori (Noguchi and Hayakawa, 2001) (see Section 3.12.3.1.1). Among genes that are upregulated by both short day conditions and the feeding of DOPA in *M. brassicae*, the most striking is an upregulated gene with high identity to a *H. virescens* gene that encodes a receptor for activated protein kinase C (RACK) (Uryu *et al*., 2003). *In situ* hybridization with a RACK probe reveals expression of this gene within a few cells in the medial protocerebral neuropile. As a member of the protein kinase C (PKC) signaling cascade, RACK has the potential to be an important gene contributing to transduction of the signals involved in diapause induction. Noguchi and Hayakawa (1997) propose that the elevation of dopamine may be key to the prevention of PTTH release.

Elevation of brain serotonin (5-hydroxytryptamine) has also been linked to diapause in several cases (Kostal *et al*., 1999; L'Helias *et al*., 2001), but not in others (Puiroux *et al*., 1990). In *C. costata*, depletion of serotonin does not alter the fly's capacity to enter larval diapause (Kostal *et al*., 1999), thus suggesting that the observed elevation of this monoamine is not essential for diapause induction.

The shutdown in the brain–prothoracic gland axis is not exclusively the result of a failure of the PTTH cells to produce or release PTTH. The prothoracic gland also becomes refractory to PTTH at this time, thus providing a double assurance that the neuroendocrine system will not provide the signal needed to promote development. Assays for PTTH activity indicate that prothoracic glands dissected from diapausing individuals are refractory to stimulation, as shown in larvae of *Calliphora vicina* (Richard and Saunders, 1987) and *O. nubilalis* (Gelman *et al*., 1992), and in pupae of *Manduca sexta* (Bowen *et al*., 1984) and *S. argyrostoma* (Richard and Saunders, 1987). This loss of competency can be rather rapid (**Figure 9a**): in *S. argyrostoma* the prothoracic glands lose their competency to produce ecdysone within a 1–2 day period at the onset of diapause (Richard and Saunders, 1987). In the larval diapause of *C. vicinia* the loss of competency is more gradual, occurring over a 6 day period, and even during diapause the gland maintains limited competency to produce ecdysone (**Figure 9b**). At termination of diapause, prothoracic gland competency is again restored quickly. When diapausing larvae of *C. vicina* are transferred from 11 to 25 °C, the prothoracic gland regains competency to produce ecdysone within 24 h (Richard and Saunders, 1987).

PTTH stimulation of the prothoracic gland in nondiapausing insects is mediated by cyclic AMP as a second messenger, but the diapausing glands of *M. sexta* (Smith *et al*., 1986) and *S. argyrostoma* (Richard and Saunders, 1987) fail to respond to cyclic AMP or agents known to elevate cyclic AMP, thus implying that the block in gland function occurs beyond the stage of cyclic nucleotide action.

Reports from several species of Lepidoptera indicate that cells of the prothoracic gland are greatly reduced in size during diapause, both the cytoplasm and nuclei are shrunken, and the mitochondria take on a swollen configuration (Denlinger, 1985). In *S. crassipalpis,* there is a slight reduction in the size of the cells in the prothoracic gland component of the ring gland, but this difference is not as conspicuous as noted in the Lepidoptera (Joplin *et al*., 1993). Results of an ultrastructural examination of the fly prothoracic gland during diapause are rather surprising. Instead of being inactive, the presence of extensive arrays of rough endoplasmic reticulum suggests that the glands remain active in protein synthesis. Pulse labeling of the ring gland further supports the contention that the gland continues to synthesize proteins during diapause. The function of this curious diapause activity remains unknown, but it would appear to be unrelated to ecdysone production since all evidence indicates that this function is shut down at this time.

Though there appears to be species variation as to whether the synthesis or release of PTTH is regulated, the net effect, a shutdown in the synthesis of ecdysteroids, is consistent. The earlier literature provides numerous examples documenting a low or undetectable ecdysteroid titer in larvae or pupae in diapause and an elevation in the ecdysteroid titer at the termination of diapause. More recent studies continue to provide evidence that this is the case, e.g., larval diapauses of *O. nubilalis* (Gelman and Woods, 1983; Gelman and Brents, 1984; Peypelut *et al*., 1990) and *Omphisa fuscidentalis* (Singtripop *et al*., 2002) and pupal diapauses of *Mamestra configurata* (Bodnaryk, 1985), *Manduca sexta* (Friedlander and Reynolds, 1992), *S. argyrostoma* (Richard *et al*., 1987), and *S. peregrina* (Moribayashi *et al*., 1988). As will be discussed below (see Section 3.12.3.2.4), some larvae periodically undergo a stationary molt during diapause, and in these cases a burst of ecdysteroid synthesis may occur during diapause and thus prompt the larva to molt. The surge in ecdysteroids that normally occurs at the end of diapause may come as two distinct waves. In *M. configurata* the release of ecdysone into the hemolymph is followed several days later by the appearance of 20E (Bodnaryk, 1985). Since these two peaks are nearly identical in size, they may simply represent the conversion of ecdysone to 20E. In *Ostrinia nubilalis* a small transient peak of 20E is followed several days later by a major peak of

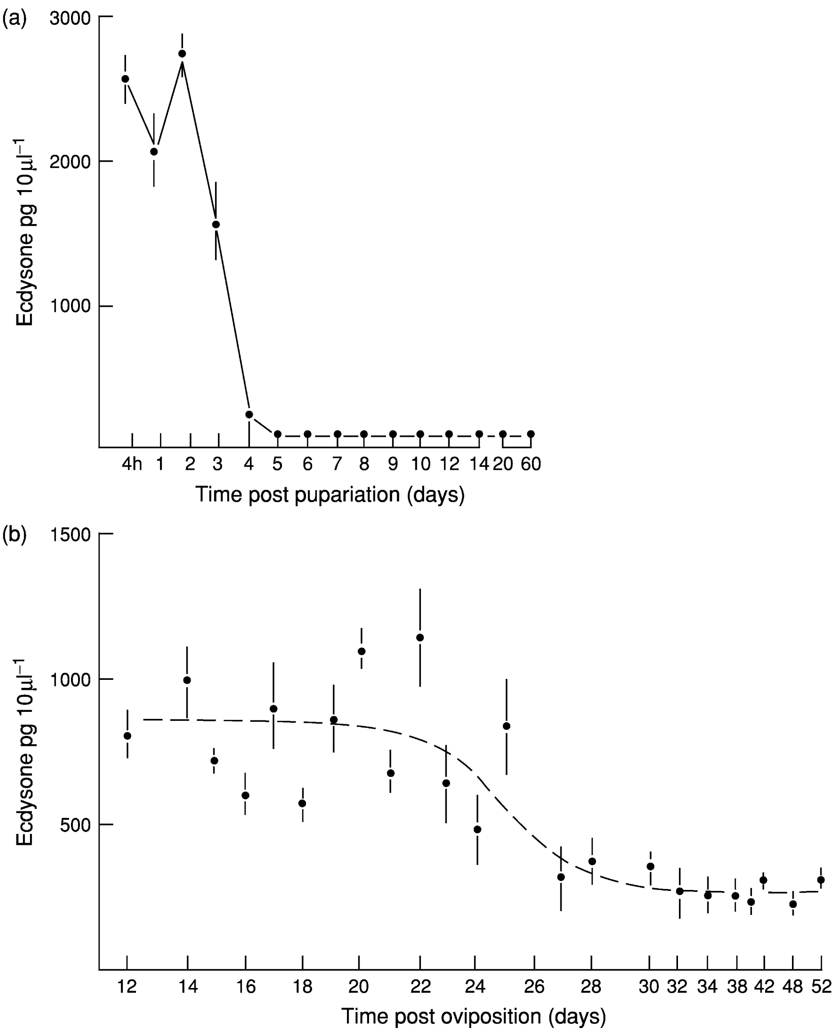

Figure 9 Decline in the competency of ring glands from diapause-destined (a) *Sarcophaga argyrostoma* and (b) *Calliphora vicina* to synthesize ecdysone in response to incubation with prothoracicotropic hormone (PTTH)-producing brains. As *S. argyrostoma* enters pupal diapause and as *C. vicina* enters larval diapause their ring glands become refractory to PTTH stimulation. (Adapted from Richard, D.S., Saunders, D.S., **1987**. Prothoracic gland function in diapause and non-diapause *Sarcophaga argyrostoma* and *Calliphora vicina*. *J. Insect Physiol.* *33*, 385–392.)

20E (Peypelut *et al.*, 1990). In this case, imaginal wing disc development is thought to be initiated by the small initial peak, but the later phases of postdiapause development require the sustained presence of 20E.

Consistent with the concept that the absence of ecdysteroids is central to maintaining the diapause state is the observation that an application of exogenous ecdysteroids or ecdysteroid mimics can terminate diapause. Again, the older literature includes numerous examples supporting this response, and more recent work continues to document this effect, e.g., larval diapauses of *O. nubilalis* (Gadenne *et al.*, 1990) and *Diprion pini* (Hamel *et al.*, 1998), and pupal diapauses of *Mamestra configurata* (Bodnaryk, 1985), *Pieris brassicae* (Pullin and Bale, 1989), and *Manduca sexta* (Friedlander and Reynolds, 1992; Sielezniew and Cymborowski, 1997; Champlin and Truman, 1998).

3.12.3.2.2. The missing pieces The role of the brain–prothoracic gland axis in diapause, as presented above, is reasonably cohesive. In a simplified version, the prothoracic gland fails to produce ecdysone because it has not been stimulated by PTTH from the brain. Yet, some pieces of information are not consistent with this simple story and remain unexplained. For *Hyalophora cecropia* the above story is just fine. The brain, when chilled, becomes activated to release PTTH and this in turn prompts the prothoracic glands to secrete the ecdysteroids needed to initiate development. Without a brain,

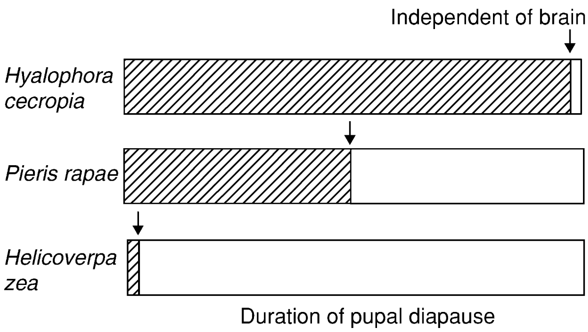

Figure 10 Time during pupal diapause at which several species are no longer dependent on the brain for initiation of adult development. (Adapted from Denlinger, D.L., **1985**. Hormonal control of diapause. In: Kerkut, G.A., Gilbert, L.I. (Eds.), Comprehensive Insect Physiology, Biochemistry and Pharmacology, vol. 8. Pergamon Press, Oxford, pp. 353–412.)

the pupa is locked into a permanent diapause. But, in several cases, this is not true (Denlinger, 1985). In *M. sexta, P. rapae*, and *Antheraea polyphemus* removal of the brain during the first month or so of diapause will produce a permanent diapause, but in later stages removal of the brain has no impact (**Figure 10**). The extreme case is noted in *Helicoverpa zea*: brain removal within the first 4 h after pupation will cause a permanent diapause, but within 24 h the diapausing pupa is already independent of the brain. Clearly the *Hyalophora cecropia* model can not explain these observations. Meola and Adkisson (1977) argue that PTTH exerts it effect very early in *H. zea*, and after receiving the PTTH signal, the prothoracic glands take on the role of the regulatory organ: high temperature (27 °C) promotes ecdysteroid synthesis, while low temperature (21 °C) prevents ecdysteroid synthesis. In these cases it is clear that one can not simply explain the end of diapause as an event triggered by the brain's release of PTTH. What is lacking is a good explanation of this peculiar interaction between the brain and prothoracic gland. What does it mean for the brain, presumably PTTH, to stimulate the prothoracic gland so early and for the gland to delay the onset of ecdysteroid synthesis by many months?

Several lines of evidence suggest that there may be differences in the way the prothoracic gland is activated in nondiapausing individuals and at the termination of diapause. In *S. crassipalpis*, cyclic AMP levels in the brain and ring gland are high in nondiapausing pupae and low in diapausing pupae at the onset of diapause, and diapause can easily be averted in the diapause-programmed pupae if cyclic AMP levels are artificially boosted around the time of expected diapause entry (Denlinger, 1985). This observation is thus compatible with other evidence suggesting that cyclic AMP is used as a second messenger for PTTH (see **Chapter 3.2**). One might then assume it would also be possible to employ this same tactic of cyclic AMP elevation to initiate development in a pupa that has been in diapause for some time. Surprisingly, this does not work. In fact, cyclic AMP injected along with ecdysteroids actually retards the termination of diapause. By contrast, cyclic GMP, which is ineffective in averting diapause, can readily break diapause by itself and will enhance the diapause-breaking effect of ecdysteroids (Denlinger and Wingard, 1978). The fact that Richard and Saunders (1987) were unable to stimulate ecdysteroid production with PTTH or cyclic nucleotides in prothoracic glands cultured from diapausing pupae of *S. argyrostoma* or diapausing larvae of *C. vicina* also suggests that the glands are somehow activated in a different way at the termination of diapause.

Although prothoracic glands dissected from *C. vicina* are competent to synthesis ecdysone within 24 h after a transfer of the diapausing larvae to a high temperature, brain–ring gland complexes cultured *in vitro* fail to gain competency when subjected to the same temperature switch (Richard and Saunders, 1987). This suggests that some additional component from another part of the body may contribute to reactivation of the prothoracic gland. The pieces of the fly puzzle are these: cyclic GMP readily breaks diapause when injected *in vivo*, but fails to activate prothoracic glands cultured *in vitro*, and the brain–prothoracic gland can regain competency in response to high temperature *in vivo*, but not *in vitro*. A minimal interpretation of these observations is that some additional prothoracicotropic factor, perhaps acting through cyclic GMP, contributes to activation of the prothoracic gland at the termination of diapause.

3.12.3.2.3. Ecdysone receptor and Ultraspiracle

Two proteins, Ecdysone receptor (EcR) and Ultraspiracle (USP), dimerize to form the functional receptor for ecdysone (see **Chapter 3.5**). Ecdysone binds to this complex, which in turn binds directly to the ecdysone response elements to elicit specific gene action. The central role for ecdysteroids in the regulation of larval and pupal diapauses suggests that these proteins could contribute to the diapause control mechanism, but thus far few experiments have addressed this question. During pupal diapause of *S. crassipalpis* expression of EcR mRNA persists throughout diapause, but the expression of EcR's dimerization partner, USP, gradually declines at the onset of diapause and is undetectable after 20 days in diapause (Rinehart *et al.*, 2001). USP transcripts

again appear in late diapause (beginning on day 50) and are further upregulated 9 h after pupae are stimulated to break diapause. This 9 h time-frame coincides precisely with the rise in the ecdysteroid titer following hexane application. It is interesting to note that upregulation of the USP transcripts at day 50 coincides with the pupa's increased sensitivity to injected ecdysteroids. This suggests the possibility that the reappearance of the USP transcript is a preparatory step, perhaps a critical one, leading to the eventual termination of diapause. In the second instar larval diapause of *Choristoneura fumiferana*, genes encoding both isoforms of EcR are expressed throughout diapause, as is the gene encoding USP (Palli *et al*., 2001). However, the ecdysone-inducible transcription factors (CHR75A and CHR75B) and hormone receptor 3 (CHR3) are not present during diapause but reappear at diapause termination.

In *M. sexta* the transcript encoding EcR disappears at the onset of diapause and reappears when diapause is terminated (Fujiwara *et al*., 1995). In the larval diapause of the midge *Chironomus tentans* EcR transcripts are detectable throughout diapause, and an increase is noted at diapause termination (Imhof *et al*., 1993). The patterns of USP mRNA expression are unknown for these two species. Although the data base remains small at this point, the results do not suggest the emergence of a universal pattern in relation to diapause. What is clear, though, is that the presence or absence of these receptor proteins could very well be an important component of the regulatory scheme for diapause. Turning off the expression of one or both of these genes could promote diapause, while the presence of these gene products is likely to be essential for the resumption of development.

3.12.3.2.4. Role of the corpora allata The early views of larval and pupal diapause focused strictly on the brain–prothoracic gland axis, leaving little reason to suspect involvement by JH. This view was challenged by a fine set of experiments on *Diatraea grandiosella* by Chippendale, Yin and their colleagues beginning in the early 1970s (review: Chippendale, 1977). What launched their work on JH was the surprising discovery that injection of ecdysteroids into a diapausing larva of *D. grandiosella* prompted a stationary larval molt rather than pupation. The stationary molt, of course, suggested the presence of JH because the larva would have been expected to pupate in the absence of JH. This suspicion of JH involvement was followed by verification that the hemolymph titer of JH remains high and the corpora allata are active during diapause. At the end of diapause, the JH titer drops, and the larva goes ahead and pupates. A similar regulatory scenario is evident in some of the *Chilo* stemborers. What these two taxa share is the fact that they both are species that undergo stationary molts during diapause, and the only way to undergo a stationary molt rather than a progressive molt is to maintain a high JH titer. The high JH titer recently reported for larval diapause in the Mediterranean corn borer, *Sesamia nonagrioides*, suggests that it too has a diapause maintained by JH (Eizaguirre *et al*., 1998).

Species that do not undergo stationary molts presumably do not need to maintain a high JH titer during diapause, and in a number of lepidopteran larvae JH appears to play no role, e.g., *O. nubilalis* and *Laspeyresia pomonella* (Denlinger, 1985). In these species JH is actually high at the onset of diapause, but the titer drops to low levels shortly after the diapause is initiated. In these species an injection of ecdysteroids elicits pupation, not a stationary molt. Why the JH titer is high at the onset of diapause is unclear, but it does not appear to be involved in the induction process. Application of JH to nondiapausing larvae at this stage does not cause the induction of larval diapause.

An application of JH can terminate larval diapause in *Omphisa fuscidentalis* (Singtripop *et al*., 2000), as reported previously for a number of other larval and pupal diapauses (Denlinger, 1985), and JH presumably exerts this effect by stimulating the prothoracic gland to produce ecdysone. There is no evidence to suggest that JH, by itself, is the natural trigger for diapause termination. A combined role for JH with ecdysteroids is, however, likely is some cases. In flesh flies, JH by itself has no effect in terminating pupal diapause, but dramatic synergism is noted when JH is applied in concert with a small dose of ecdysteroid (Denlinger, 1979). When diapause is terminated naturally in flesh flies, a small peak of JH activity precedes the sustained elevation of the ecdysteroid titer, thus the combined application of JH and ecdysteroid likely is an effective mimic of the natural reactivation process.

The JH may contribute to the metabolic events occurring during pupal diapause, but it does not appear to play a regulatory role in the induction or termination of diapause. In flesh flies, JH is involved in regulating metabolic cycles that persist during diapause (Denlinger *et al*., 1984). In these flies the metabolic rate is not constant but instead occurs in cycles having periodicities of 4–6 days. These cycles are driven by JH. The hemolymph JH titer progressively increases during the trough of the cycle, reaches a critical point, triggers a bout of high oxygen consumption, and then drops precipitously. The

rapid decline in the JH titer is aided by a rise in JH esterase (Denlinger and Tanaka, 1989). When the ring gland containing the corpora allata is removed, the diapausing pupae become acyclic. Application of a high dose of JH analog to the pupae just before diapause will not alter the diapause fate of the pupa, but such pupae fail to exhibit oxygen consumption cycles and instead consume oxygen at a high rate throughout diapause. Pupae treated this way have a much shorter diapause, presumably because their high metabolic rate has prematurely exhausted their energy reserves. This conclusion assumes a mechanism used by the pupae to monitor and respond to depleted energy reserves (Denlinger *et al*., 1988).

3.12.3.2.5. A role for diapause hormone? Diapause hormone (DH) is well known for its role in diapause induction in *B. mori* (see Section 3.12.3.1.1), but attempts to induce diapause in other species with DH have failed. Thus, DH appeared to be a neuropeptide with some other primary function that was simply captured by *B. mori* to serve as a diapause regulator (Denlinger, 1985). We now know, however, that a gene encoding a DH-like sequence is present and indeed expressed in all Lepidoptera that have been examined, even those that lack an embryonic diapause. DH and pheromone biosynthesis activating neuropeptide (PBAN), along with several additional subesophageal ganglion neuropeptides (SGNPs), are encoded by a common precursor (Sato *et al*., 1993; Ma *et al*., 1994). However, the function of this DH-like peptide in species other than *B. mori* has remained a puzzle.

Might DH contribute to diapause in other species? DH-like peptides from *Helicoverpa armigera* (Zhang *et al*., 2004) and *Heliothis virescens* (Xu and Denlinger, 2003) appear to have no stimulatory effect on diapause induction, but quite surprisingly, diapausing pupae of both species readily respond to the DH-like peptides by terminating diapause. This, of course, could represent a nonspecific effect, but nonamidated forms of DH and other injected proteins fail to terminate diapause, thus suggesting that the effect is specific for DH. The possibility that a drop in DH contributes to diapause induction is further supported by the observation that expression of the mRNA encoding DH-PBAN declines at the onset of larval wandering behavior and remains low throughout pupal diapause, whereas expression remains high in larvae and pupae not destined for diapause. When diapausing pupae of *Helicoverpa armigera* are transferred to high temperatures to terminate diapause, the mRNA encoding DH-PBAN is quickly elevated (Zhang *et al*., unpublished data). In *Heliothis virescens*, Northern blots indicate that the DH-PBAN message is most highly expressed in the subesophageal ganglion complex (Xu and Denlinger, 2003), and this is supported by immunocytochemical evidence in *Helicoverpa armigera* (Zhang *et al*., unpublished data). The hemolymph titer of DH-like peptide is also much higher in nondiapausing pupae than in diapausing ones (Zhang *et al*., unpublished data). Injection of DH into diapausing pupae prompts a major increase in hemolymph ecdysteroids 3–7 days after DH injection. Although this is a rather radical concept of DH action that will need further validation, the current evidence from these noctuid moths is consistent with a drop in DH being essential for pupal diapause induction and DH elevation serving as a possible trigger for the ecdysteroid surge needed for diapause termination.

3.12.3.2.6. Associated changes in gene expression The endocrine mechanism that dictates the diapause fate of the insect can be viewed as a developmental switch that brings into play the upregulation and downregulation of huge suites of genes. Some diapause-associated patterns of gene expression may actually be upstream of the endocrine switch, while many others are likely to be downstream events set in motion by the endocrine program. We remain in an early stage of deciphering this vast gene regulatory hierarchy, and currently we have a limited view of the genes involved. This section serves to summarize our current understanding of a small sampling of the genes likely to be involved in larval and pupal diapause.

Diapause represents both a shutdown in the expression of many genes as well as the upregulation of a smaller subset of genes (Joplin *et al*., 1990; Flannagan *et al*., 1998). Estimates based on two-dimensional gel electrophoresis of proteins, subtractive hybridization, and differential display of mRNA suggest that ~4% of the genes in flesh fly pupae are diapause upregulated. Representative patterns of gene expression noted during pupal diapause in the flesh fly *Sarcophaga crassipalpis* are shown in **Figure 11**. The expression patterns fall into several discrete categories (Denlinger, 2002): genes unaffected by diapause, genes downregulated throughout diapause, genes upregulated throughout diapause, early diapause genes, late diapause genes, and those expressed intermittently throughout diapause.

Genes unaffected by diapause in the flesh fly include those encoding ecdysone receptor (EcR), heat shock 70 cognate protein (HSC 70), and 28S ribosomal protein. In the larval diapause of *Choristoneura fumiferana*, the genes encoding S-transferase and ubiquitin are in this category (Feng *et al*., 2001; Palli *et al*., 2001). Presumably many genes essential

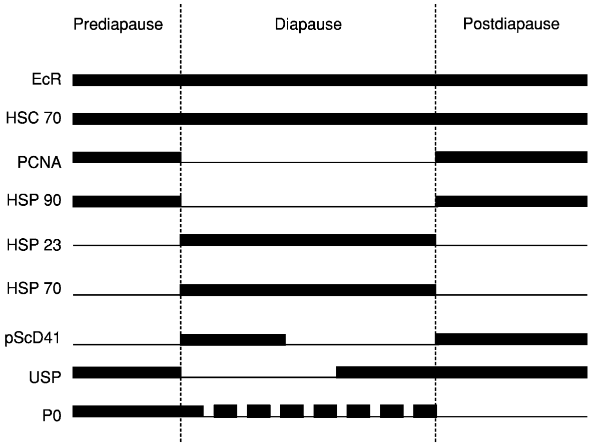

Figure 11 Representative patterns of gene expression noted in the flesh fly *Sarcophaga crassipalpis* in relation to pupal diapause. Proteins encoded by the genes are indicated on the left of the diagram. Categories include genes that are not influenced by diapause (*ecr* and *hsc70*), genes that are downregulated (*pcna* and *hsp90*), genes that are upregulated throughout diapause (*hsp23* and *hsp70*), early diapause genes (*pScD41*), late diapause genes (*usp*), and genes expressed intermittently during diapause (*po*). (Reproduced with permission from Denlinger, D.L., **2002**. Regulation of diapause. *Annu. Rev. Entomol. 47*, 93–122.)

for both diapause and nondiapause activities will be in this category.

Diapause downregulated genes represent another large category. In the flesh fly, such genes include those that encode proliferating cell nuclear antigen (PCNA) and a 90 kDa heat shock protein (Hsp90). In *C. fumiferana*, a mitochondrial phosphate transport protein is downregulated (Feng *et al.*, 1998). Although many genes in this category may simply reflect the major shutdown in metabolism that characterizes diapause, some of the downregulated genes may be of particular importance from a regulatory perspective. One such gene is *pcna*, a gene involved in cell cycle regulation. The brains of flesh fly pupae are in a G_0/G_1 cell cycle arrest, and the downregulation of *pcna* may contribute to this arrest (Tammariello and Denlinger, 1998).

Among the most highly diapause-upregulated genes in the flesh fly are those that encode the 70 kDa heat shock protein (Hsp70) (Rinehart *et al.*, 2000) and Hsp23 (Yocum *et al.*, 1998). Both of these genes are quickly upregulated at the very onset of diapause and remain upregulated throughout diapause, even at moderate temperatures. When diapause is terminated with hexane, both genes are downregulated within 6 h. This response is unusual in several ways: these are the heat-inducible forms of these genes, yet they are in this case developmentally regulated; instead of being expressed briefly as they are under stress-induced conditions, here expression persists for months. There is also a dissynchrony in this heat shock protein response. In response to most environmental stresses all of the heat shock proteins are synchronously turned on, but during diapause, Hsp23 and Hsp70 are upregulated, while Hsp90 is actually downregulated (Rinehart and Denlinger, 2000). The upregulation of Hsp70 appears to be common during diapause in other insects as well (Denlinger *et al.*, unpublished data), and it is speculated that this upregulation may have two functions (Denlinger *et al.*, 2001): (1) upregulation of heat shock proteins can be incompatible with further development, thus this upregulation may serve to bring about the halt in development that characterizes diapause, and/or (2) the presence of heat shock proteins during diapause may serve a cryoprotective role during the low temperatures the fly is likely to encounter during its overwintering diapause. In support of this second function is the observation that knocking down Hsp70 expression during diapause by use of RNA interference does indeed reduce the fly's low temperature tolerance (Rinehart, unpublished data).

Unlike the heat shock proteins that are upregulated throughout diapause, expression of a few genes is restricted to early diapause. Early-diapause genes are of interest because they could be important in the processes that shut down development. A gene in this category in flesh flies is one that encodes cystatin, a cysteine proteinase inhibitor (Goto and Denlinger, 2002a). Its mRNA is abundant for the first 20 days of diapause but then remains low for the remainder of diapause. Another gene in this category encodes a retrotransposon (Denlinger, 2002).

Genes restricted in their expression to late diapause, the late-diapause genes, are also of potential interest because such genes could be involved in the events leading to diapause termination. The gene encoding USP (see Section 3.12.3.2.3) is in this category, and we speculate that its upregulation late during pupal diapause in flesh flies may help to set the stage for diapause termination (Rinehart *et al.*, 2001). In larvae of *C. fumiferana* the gene that encodes defensin begins to rise 5 weeks after the larvae are placed at 2 °C for diapause maintenance (Palli *et al.*, 2001).

One final category of genes evident in the diapause of flesh flies includes genes that are intermittently expressed during diapause. One gene noted so far is a gene that encodes 60S ribosomal protein PO, an apurinic/apyrimidinic endonuclease (Craig and Denlinger, 2000). Expression of this gene appears to be linked to the infradian cycles of oxygen consumption characteristic of *Sarcophaga* diapause. During periods of high oxygen consumption

expression levels of this gene are low, but during the intervening days when oxygen consumption is low, the gene is highly expressed. Interestingly, this is a gene known to be involved in hypoxic stress responses.

3.12.3.3. Hormonal Basis for Adult Diapause

The central feature of adult diapause is a cessation in reproduction. For females this implies an arrest in oocyte development, and in males the most conspicuous feature is their failure to mate with receptive females. The status of the testes is not a consistently reliable indicator of diapause in males (Pener, 1992): in some cases the testes are underdeveloped, while in other cases the testes may be full of mature sperm cysts. In both males and females the accessory glands are usually reduced in size during diapause. Although a period of long-distance flight may precede the entry into diapause, once the adults arrive at their diapause site, flight muscles typically degenerate for the duration of diapause and then regenerate when diapause is terminated. Adults remain fairly inactive in diapause, but some local movements may be noted. Mating may occur either before the entry into diapause or after diapause has been completed. When mating occurs prior to diapause, the males usually die without entering diapause and only the females bridge the diapause period. In cases where both sexes diapause, mating usually occurs only after diapause has been terminated.

Most of the early work on the hormonal control of adult diapause focused on JH. The pioneering work on adult diapause, initiated in the late 1950s by Jan de Wilde and his colleagues in the Netherlands, utilized the Colorado potato beetle as their model system (de Kort, 1990). They observed that the JH titers in diapause-programmed *Leptinotarsa decemlineata* decrease after adult emergence, remain low throughout diapause, and then rise after termination of diapause. Further evidence supporting the role of JH in adult diapause was provided by the responsiveness of diapausing adults to JH, histological studies of the corpora allata (CA), and experimental manipulations of the CA. The application of synthetic JH and JH analogs to diapausing females prompts egg-laying (although such periods are not sustained). The CA from diapausing *L. decemlineata* are small and inactive. Surgical removal of the CA induces a diapause-like state in long-day beetles (those not programmed for diapause): they stop feeding, leave the food, and burrow into the soil. Chemical destruction of the CA in long-day beetles with precocene II elicits the same diapause-like response. In nondiapausing adults, cauterizing the pars intercerebralis, the region of the brain that controls CA activity, also induces a diapause-like state. This same surgery performed with diapausing adults blocks the beetle's ability to become reproductively active when placed under long daylengths (the environmental signal used to promote reproduction). Severing the axons between the pars intercerebralis and the CA does not appear to alter the diapause decision, thus suggesting that the CA in this species is under hormonal, rather than neural, control.

In the early experimental years there would have been no reason to suspect a role for ecdysteroids as a regulator of adult diapause because the well-known larval source of ecdysteroid synthesis, the prothoracic gland, degenerates in adults. But the discovery in the late 1970s that adults can produce ecdysteroids from other tissues such as ovaries raised the possibility that ecdysteroids could also be involved in the regulation of reproductive events. In the Colorado potato beetle, the hemolymph ecdysteroid titer is nearly twice as high in diapause-programmed beetles as it is in nondiapause-programmed beetles, but the titer drops sharply a few days after adult eclosion. The functional significance of this elevated ecdysteroid titer associated with diapause has not been determined.

While the scheme for the hormonal control of adult diapause that has been developed from experiments in *L. decemlineata* is applicable to many species that diapause as adults, there are also clear species differences. These differences may include whether both sexes enter diapause, sexual distinctions in the environmental cues used for regulating diapause, and the formation of stable intermediate phenotypes that lie somewhere between being fully sexually active and being complete inactive. The regulatory mechanisms controlling the CA during adult diapause vary among species. The brain's regulation of the CA can be either hormonal as in *L. decemlineata* or neural as in *Pyrrhocoris apterus*, *Tetrix undulata*, and *Locusta migratoria*. The limited number of species examined through 1985 indicated clear unifying themes within adult diapause, yet distinct differences between species were also apparent.

3.12.3.3.1. Role of the corpora allata Recent research on the endocrine basis of adult diapause continues to focus primarily on the role of JH. In substantially more species we now have new or additional evidence that JH plays a major role in regulating diapause, e.g., the green bug *Plautia stali* (Kotaki and Yagi, 1989), the pear psylla *Cacopsylla pyricola* (Krysan, 1990), the Colorado potato beetle *Leptinotarsa decemlineata* (Koopmanschap *et al.*,

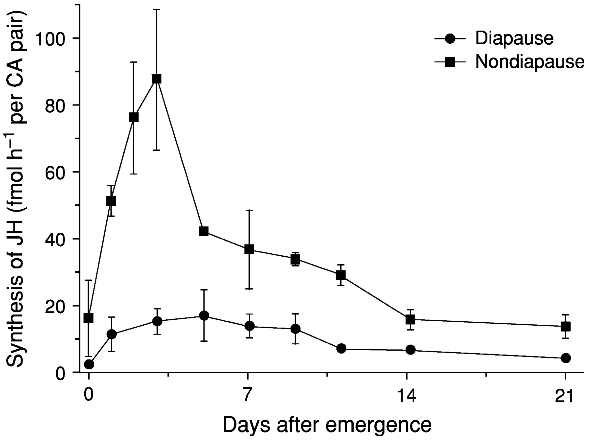

Figure 12 *In vitro* activity of the corpora allata (CA) from diapausing and nondiapausing females of the mosquito *Culex pipiens* on different days following adult emergence. (Reproduced with permission from Readio, J., Chen, M.-H., Meola, R., **1999**. Juvenile hormone biosynthesis in diapausing and nondiapausing *Culex pipiens* (Diptera: Culicidae). *J. Med. Entomol. 36*, 355–360.)

1989), the fungus beetle *Stenotarsus rotundus* (Tanaka *et al*., 1987), the beetle *Aulacophora nigripennis* (Watanabe and Tanaka, 1998), the butterfly *Speyeria idalia* (Kopper *et al*., 2001), the bumblebee *Bombus terrestris* (Larrere *et al*., 1993), the mosquito *Culex pipiens* (Readio *et al*., 1999), and the blowfly *Protophormia terraenovae* (Matsuo *et al*., 1997).

Earlier results arguing a role for JH in regulating the adult diapause of *C. pipiens* were based on the ability of JH applications to terminate diapause; more recently this evidence was supplemented by demonstrating that cultured CA dissected from diapausing females secrete very little JH (**Figure 12**), while those dissected from nondiapausing females are quite active, especially during the first week after adult eclosion (Readio *et al*., 1999). Females of *C. pipiens* that are allatectomized and then transferred to diapause-terminating conditions remain in a diapause-like state and fail to initiate the blood feeding noted in control groups. In *P. terraenovae* JH applications or implantations of active CA into diapausing adults are fully capable of initiating ovarian development (Matsuo *et al*., 1997).

The CA, of course, does not function autonomously. Activity of the CA is coordinated by the brain, and the brain exerts its control through both hormonal and neuronal conduits. Active suppression of the CA by the brain during diapause has been demonstrated in the following insect orders: Coleoptera: *L. decemlineata* (Khan *et al*., 1983, 1988); Diptera: *P. terraenovae* (Matsuo *et al*., 1997); Heteroptera: *Plautia stali* (Kotaki and Yagi, 1989), *Riptotus clavatus* (Morita and Numata, 1997a), *Pyrrhocoris apterus* (Hodkova *et al*., 2001); Orthoptera: *Locusta migratoria* (Okuda and Tanaka, 1997). In the diapause of *Protophormia terraenovae* the inhibition is maintained by neurons that originate in the pars lateralis and terminate within the CA (Shiga and Numata, 2000), but in several other species, including *Pyrrhocoris apterus* (Hodkova, 1994), the inhibition appears to originate in the pars intercerebralis. The diapause program may actually influence the organization of the synapses: rearing *Leptinotarsa decemlineata* throughout its life under short-day conditions boosts both the number and activity of neurosecretory synapses within the CA as compared to beetles reared under long-day conditions (Khan and Buma, 1985). Hormonal control of the CA is also evident in a number of species. CA activity in diapausing *Locusta migratoria* is suppressed by neuropeptide(s) stored in the corpora cardiaca (CC) (Okuda and Tanaka, 1997). Neural regulation of the CA during diapause may not be as simple as the presence or absence of an allatostatin. Brain extracts from both diapausing and nondiapausing *P. apterus* stimulate increased JH production in CA from nondiapausing donors but has no effect on JH synthesis in CA from diapausing donors (Hodkova *et al*., 1996). Hodkova *et al*. (1996) speculated that CA from diapausing adults may lack receptors for allatotropins, or there may be a high level of an allato-inhibiting factor in the CA or CC that blocks the action of the allatotropins. Extracts of the brain–suboesophageal ganglion–CC–CA complex from diapausing *P. apterus* inhibit the CA activity of *Plautia stali,* indicating that this neurosecretory complex from diapausing bugs may contain both allato-inhibiting and allato-stimulating factors (Hodkova *et al*., 1996).

The JH hemolymph titer is a function of both JH synthesis and its degradation (de Kort and Granger, 1996). JH esterases (JHE) play a central role in regulating the JH titer in diapause-destined adults of *Leptinotarsa decemlineata*. There is an inverse relationship between the JH hemolymph titer and JHE activity in prediapausing adults, with peak esterase activity occurring just prior to diapause initiation. This peak in JHE activity contributes to the low JH titer noted during the first 2 days of adult life (Kramer, 1978). The effect of JH on JHE activity is indirect and appears to require a factor from the brain. JHE isolated from the hemolymph of fourth instar larvae of *L. decemlineata* is a dimer consisting of two 57 kDa subunits (Vermunt *et al*., 1997a). cDNA clones of two different JHEs have been isolated from fourth instar larvae (Vermunt

et al., 1997b, 1998). JHE-A appears to encode the protein first isolated from the hemolymph, whereas the JHE-B encodes a protein that does not appear to be secreted into the hemolymph. Significant levels of expression of JHE-A are detected in the brain of fourth instar larvae and fat body of both fourth instar larvae and short-day adults; low expression is noted in long-day adults (Vermunt *et al.*, 1999). Treating diapause-destined day 1 adults with the JH analog pyriproxyfen strongly suppresses JHE-A expression. JHE-A sensitivity to pyriproxyfen decreases as beetles near diapause initiation. Vermunt *et al.* (1999) conclude that JHE activity in the hemolymph is critical for the initiation of diapause in the Colorado potato beetle. However, a role for JHEs in regulation of the JH titer appears not to be essential for some other cases of adult diapause. In the locusts *Nomadacris japonica* and *Locusta migratoria* there appear to be no differences in JHE hemolymph activity between long-day and short-day adults (Okuda *et al.*, 1996).

Though the evidence supporting involvement of JH in reproductive diapause is compelling, there are also results indicating that the absence of JH is not the exclusive cause of diapause induction and maintenance. Results, even in the Colorado potato beetle, suggest that lack of JH cannot account for all the observations. The fact that JH application, at best, can stimulate only a short burst of oviposition in diapausing females suggests that the actual termination of diapause requires more than a single boost in the JH titer. This observation has usually been interpreted as the need for sustained stimulation of the CA by the brain (Denlinger, 1985). Thus, a minimal interpretation is that, at the end of diapause, the brain must become reactivated in order to promote JH synthesis by the CA. Brain activation clearly needs to precede activation of the CA, and quite possibly the brain independently directs specific events that are associated with diapause termination but occur prior to activation of the CA. That such may be the case is evident from the observation that adults of *Leptinotarsa decemlineata* actually dig their way out of the soil prior to activation of the CA (Lefevere *et al.*, 1989). This suggests that activation of the CA may be the consequence of diapause termination, rather than the cause.

The regulatory scheme for males is not always the same as that in females. In *Pyrrhocoris apterus* (Hodkova, 1994) and *Protophormia terraenovae* (Tanigawa *et al.*, 1999), regulation of diapause in females clearly involves the CA, but the CA does not appear to be involved in males. Allatectomy has little effect on the manifestation of diapause in the males; they can respond to photoperiod and display mating behavior even in the absence of a CA. The inhibitory center regulating mating behavior resides in the brain's pars intercerebralis, but this important inhibitory pathway does not involve the CA.

When the CA are involved in regulating diapause, they presumably preside over the whole diapause syndrome, not just the regulation of reproduction. This appears to be the case in *Pyrrhocoris apterus,* a species in which photoperiod dictates not only the reproductive status of the female, but also the profile of phospholipid molecules in cell membranes (Hodkova *et al.*, 2002). The unique winter pattern of phosphatidylethanolamines, associated with cold hardening, is programmed by short daylength, not low temperature. Nondiapausing females deprived of their CA assume the lipid profile normally associated with diapausing females. Similarly, earlier studies with the Colorado potato beetle demonstrated involvement of the CA in determining the status of flight muscles during diapause.

3.12.3.3.2. Role of ecdysteroids The role of ecdysteroids in the regulation of adult diapause has been investigated most thoroughly in *Drosophila melanogaster.* A reproductive arrest occurs at the previtellogenic stage of ovarian follicular development in females of *D. melanogaster* that eclose under short day length and low temperatures (Saunders *et al.*, 1989). Yolk proteins (YPs) are present in the hemolymph of diapausing females, but the oocytes fail to incorporate the YPs (Saunders *et al.*, 1990). The ecdysteroids are proposed to activate endocytosis at the termination of diapause and thus allow the initiation of vitellogenesis (Richard *et al.*, 1998). The evidence for this intriguing scenario is compelling.

During diapause the ovaries produce low level of ecdysteroids; the rate of synthesis begins to increase 4 h after transferring the flies to 25 °C to terminate diapause, and reaches maximum levels by 12 h (Richard *et al.*, 1998). Injection of 20E terminates diapause in a dose-dependent manner as measured by ovarian maturation (Richard *et al.*, 2001b). YP uptake by the oocytes is by a receptor-mediated endocytotic mechanism (Bownes *et al.*, 1993), a mechanism that involves at least three key proteins. Clathrin coats the pit, and adaptin binds to both clathrin and the transmembrane YP receptor (Gao *et al.*, 1991; Smythe and Warren, 1991). Once the vesicle is internalized the vesicle breaks down, and the clathrin and adaptin are recycled (Gao *et al.*, 1991). Clathrin, adaptin, and YP receptor are undetectable by immunostaining in diapausing females. Terminating diapause by transferring the flies to 25 °C or injecting them with 20E induces the expression of clathrin, adaptin, and the YP receptor

in nurse cells adjacent to the oocytes (Richard *et al.*, 2001a). Incubating ovaries from diapausing females with 20E fails to induce the expression of clathrin, adaptin, or the YP receptor, indicating that diapause termination is not regulated by the ovaries and that some external factor is needed (Richard *et al.*, 2001a).

How can these ecdysteroid results be reconciled with the huge body of data suggesting that vitellogenesis in higher Diptera is mediated by JH? Application of JH III or JHB_3 to diapausing adults of *D. melanogaster* does indeed break diapause (Saunders *et al.*, 1990), but this response is perhaps an indirect effect caused by JH triggering the ecdysteroid-mediated initiation of vitellogenesis (Richard *et al.*, 1998, 2001b). When flies are transferred to diapause-terminating conditions, it is the edysteroid titer that goes up quickly (within hours), while the JH titer remains low.

Roles for ecdysteroids are suggested in a number of other species as well, but the results are sometimes conflicting. Significantly lower ecdysteroid titers are reported for diapausing females of *Locusta migratoria* than in nondiapausing females (Tawfik *et al.*, 2002a), a result that is consistent with the diapause of *D. melanogaster.* The ecdysteroid titer in *L. migratoria* fluctuates between 22 and 40 ng ml^{-1} in diapausing females, whereas the titer reaches a peak of 354 ng ml^{-1} in 18–22 day old nondiapausing females. Treating diapausing females with three consecutive application of JH III induces ovarian development and increases ovarian and hemolymph titers of ecdysteroids to levels similar to those noted in sexually active females (Tawfik *et al.*, 2002a). This relationship between the ecdysteroid titer and diapause induction is, however, opposite of that noted for *Leptinotarsa decemlineata* (Briers and de Loof, 1981): in the beetles, high titers of ecdysteroids are noted in diapause-destined beetles shortly after adult eclosion but then drop within the first week, whereas the titer is initially low in nondiapausing adults and then increases in females at the onset of reproduction. During diapause, the ecdysteroid titer gradually increases (Briers *et al.*, 1982). This may be essential for diapause termination. Interestingly, an injection of a combination of 20E and JH is much more effective in breaking diapause than either hormone by itself (Lefevere, 1989), a response also noted for pupal diapause termination in flesh flies (Denlinger, 1979). Lefevere *et al.* (1989) suggest that the ecdysteroid injection enhances diapause termination by blocking the activation of JHE, thus facilitating elevation of the JH titer.

A role for ecdysteroids has also been proposed for diapause in *P. apterus* (Sauman and Sehnal, 1997). Under long-day conditions, maturation of the male accessory glands and testes of *P. apterus* occurs during the fourth nymphal instar. Injecting an ecdysteroid (makisterone A) or implanting brain–suboesophageal ganglion complexes from long-day nymphs into early fourth instar nymphs reared at short days induces sexual development in the normally immature reproductive tract. Sauman and Sehnal (1997) conclude that the prediapause physiology in the fourth instar nymph of *P. apterus* is regulated by ecdysteroids and neurohormones, an observation that is consistent with other reports showing a low ecdysteroid titer contributing to the diapause fate of the adult.

It seems unlikely that adult diapause will prove to be based simply on either a JH or ecdysteroid deficiency. Most likely, both hormones are involved in orchestrating this response. In all of the above examples showing evidence for ecdysteroid involvement, JH also has been implicated in the regulation of reproduction and diapause.

3.12.3.3.3. Associated changes in gene expression Diapause-associated genes isolated thus far fall into four broad categories. The first category consists of genes that encode proteins having a putative regulatory function, e.g., the genes that encode the JHEs isolated from *L. decemlineata*. JHEs are involved in regulating the JH titer and their expression appears to be critical for the initiation of diapause in *L. decemlineata* (see Section 3.12.3.3.1). cDNA clones for *JHE-A* and *JHE-B* have been isolated and characterized: each contains an open reading frame encoding a deduced protein of 515 amino acids with 77% identity to each other (Vermunt *et al.*, 1997b, 1998). Both of the deduced proteins have a similar signaling peptide consisting of 24 amino acids. Southern blot analysis indicates that the *L. decemlineata* genome contains only single copies of *JHE-A* and *JHE-B* (Vermunt *et al.*, 1998).

The second category of genes includes those that encode proteins having protective functions. Overwintering insects face a number of environmental and biological challenges. Besides the well-documented threats of low temperature exposure and desiccation, insects are subjected to various pathogens during diapause. Using subtractive hybridization Daibo *et al.* (2001) isolated two diapause-upregulated transcripts from *Drosophila triauraria* with high identities to drosomycin, the antifungal protein family of *D. melanogaster.* Both clones share an identical 3′ untranslated region (UTR) and open reading frame but have unique 5′ UTRs, indicating that the two clones are separate members of the same family. Analysis of the two deduced proteins

from *D. triauraria* and members of the *D. melanogaster* drosomycin family reveals that they share a specific arrangement of eight cysteines, a signaling peptide, and a Knot 1 domain (Daibo *et al*., 2001).

Bacterial infection in *Aedes aegypti*, *A. albopictus*, and *D. melanogaster* induces expression of the iron binding protein transferrin (Yoshiga *et al*., 1999), and this transcript is also upregulated during adult diapause in *R. clavatus* (Hirai *et al*., 1998). When diapause is terminated with the JH analog methoprene, expression of the transferrin transcript is suppressed. Yet the protein persists in the fat body and hemolymph for some time after diapause is terminated (Hirai *et al*., 2000).

Another group of protective proteins noted during adult diapause is the heat shock proteins, highly conserved proteins that are induced in response to protein denaturation and developmental cues. In nonstressed cells, heat shock proteins serve as molecular chaperones, assisting in protein folding and the assembly of protein complexes. During stress heat shock proteins inhibit formation of and help dissolve protein aggregates, refold proteins, and target certain proteins for degradation (Parsell and Lindquist, 1993; Denlinger *et al*., 2001). *Leptinotarsa decemlineata* has at least two members (*Hsp70A* and *B*) of the inducible 70 kDa Hsp family (Yocum, 2001). *Hsp70A,* but not *Hsp70B,* is upregulated during diapause at normal rearing temperatures. Differential expression of these two *Hsp70*s is also seen in their response to low temperature exposure. Following a cold shock at −10 °C for 2 h, diapausing beetles express high levels of *Hsp70B* during recovery at 15 °C, but *Hsp70A* expression is only modestly increased (Yocum, 2001).

The genes that encode storage proteins represent a third category of genes associated with adult diapause. Genes encoding various classes of these proteins are expressed as a normal part of the diapause program in insects that diapause as adults (see Section 3.12.2.4).

The final class of genes associated with adult diapause are genes whose functions remain unknown. In *L. decemlineata* trace levels of *diapause-associated transcript* (*DAT*)*-1* and *DAT-2* are first detected 3 days postemergence in diapause-destined adults. Expression levels of these transcripts increase on day 6 postemergence and remain high for at least 60 days into diapause. On day 12 postemergence a low level of *DAT-3* is detected. Its level of expression increases on day 15 and remains high for at least 60 days into diapause (Yocum, 2003). The expression patterns for *DAT-1*, *DAT-2*, and *DAT-3* clearly demark two preparatory physiological events as the beetles enter diapause. In the leaf beetle *Gastrophysa atrocyanea* a 220 kDa glycoprotein of unknown function appears in the hemolymph at the onset of diapause and disappears at the end of diapause (Ichimori *et al*., 1990). Although the functions of these proteins remain unknown, the genes and/or proteins currently prove useful as biomarkers for diapause and for the timing of physiological events during diapause development.

3.12.4. Parallels to Other Dormancies

Diverse endocrine mechanisms are capable of halting development at different developmental stages and in different species that enter diapause at the same stage. And, sometimes the same net effect, diapause, is elicited by contrasting responses to the very same hormone. For example, a shutdown in ecdysteroid production is key to most pupal diapauses, but an elevation in ecdysteroids elicits diapause in pharate first instar larvae of the gypsy moth. Similarly, the absence of JH characterizes many adult diapauses, while some larval diapauses are maintained by a high JH titer. Progression through the different stages of embryonic and postembryonic development and the initiation of reproduction by the adult is orchestrated by a well-defined series of endocrine events requiring periods of hormone release and other equally important phases of hormone absence. This requirement for precisely timed periods of hormone presence or absence to elicit uninterrupted development suggests that nearly any interruption in this normal sequence could lock the insect into a developmental arrest at the point of interruption. This is presumably why we observe diverse endocrine mechanisms causing the same developmental shutdown we recognize as diapause. Presumably, this means that the endocrine control mechanism for halting development has evolved independently numerous times. Certainly there are taxa in which the diapause stage and the control mechanism are highly conserved. For example, all the flesh fly species (Sarcophagidae) from around the temperate and tropical world that have a diapause rely on a pupal diapause that represents a shutdown in the brain–prothoracic gland axis, thus suggesting a highly conserved trait within this family. By contrast, different members of the Drosophilidae are known to enter diapause as larvae, pupae, and adults, a feature suggesting that the endocrine basis for diapause has evolved several times within this taxon.

The challenge to identify a unifying endocrine basis for diapause becomes even more difficult when one seeks parallels in the endocrine control mechanisms for dormancies in nonarthropods. A connection between the insulin-like receptor *daf-2* in the production of dauerlarvae of the nematode *Caenorhabditis*

elegans (Kimura *et al*., 1997; Lee *et al*., 2003) and the involvement of a homologous receptor that influences JH synthesis in *D. melanogaster* (Tatar *et al*., 2001; Tatar and Yin, 2001) offers a tantalizing connection with some adult diapauses, but the fact that JH is not an active player in many forms of insect diapause suggests that this connection may not be applicable to all insect diapauses. It is quite likely that many different nonarthropod species, like the insects, will have tapped into diverse endocrine mechanisms to regulate their development and arrests of development.

This argument, however, does not preclude the possibility that, at the molecular level, diapause and other forms of dormancy may target the same or similar cellular processes to bring about a developmental arrest. Several results already hint of some commonality to the molecular events associated with diapause. For example, the diapause-associated upregulation of genes encoding heat shock proteins was first noted in flesh fly pupae, but heat shock protein upregulation during insect diapause has now been documented, not only in several pupal diapauses, but also in embryonic, larval, and adult diapauses of other insects, as well as in the dormancies of brine shrimp, nematodes, and some plants (Denlinger *et al*., 2001). This common feature possibly represents a widespread contribution of heat shock proteins to cellular defense and/or a contribution to the mechanism for shutting down development. Another feature that would appear to be an essential cellular event common to most diapauses is a shutdown of the cell cycle (Tammariello, 2001). Again, there may be diversity in the phase of the cell cycle that is arrested (e.g., G_0/G_1 in pupae of *Sarcophaga crassipalpis,* G_2 in pupae of *Manduca sexta* and in embryos of *Bombyx mori*) and in the cell cycle regulator that is targeted, but the overall targeting of the cell cycle is a likely ultimate target of whatever endocrine mechanism is utilized.

In numerous plant and animal taxa cellular changes in pH can induce or terminate the dormant state (Footitt and Cohn, 2001). Most commonly an increase in cellular pH is associated with induction of the dormant state, while cellular acidification is associated with termination of dormancy. Diapause in quite a few insects can also be terminated by pH change, but no convincing evidence has been provided to show that pH change is part of the normal sequence of events regulating insect diapause. Yet the widespread reliance upon pH changes to regulate dormancies in other systems suggests that this is a mechanism worthy of further consideration.

Evidence from *D. melanogaster* suggesting that elevation in nitric oxide (NO) can reversibly arrest embryonic development and create a diapause-like state (Teodoro and O'Farrell, 2003) raises the intriguing question whether this important molecule could be part of a general signaling pathway involved in diapause. NO's ability to rapidly shut down gene expression and the turnover of RNA and protein products is a feature that could be exploited by insects to initiate a developmental arrest. However, there is yet no evidence indicating such a link with a naturally occuring diapause. Although NO or pH changes may not ultimately prove to be the target molecule or mechanism common to diverse diapauses, these observations raise the specter that the wealth of hormonal regulators may eventually be reduced to a simple, conserved response at the cellular level.

3.13 Endocrine Control of Insect Polyphenism

K Hartfelder, Universidade de São Paulo,
Ribeirão Preto, Brazil
D J Emlen, University of Montana, Missoula,
MT, USA

3.13.1. Polyphenism and Polymorphism: Discontinuity in the Variation of Insects

Historically, the terms polymorphism and polyphenism have the same meaning, namely intraspecific variation in sets of characters. This phenomenon is seen as an adaptive response that allows genotypes to track short-term cycles of environmental variation and, at the same time, maintains cohesiveness of adapted gene complexes. With recent advances in population genetics, enzymology, genomics, and proteomics the term polymorphism has now gained a much wider meaning. It has come to denote variation in nucleotide sequences in general. This genetic variation may or may not have consequences for phenotypic character states, depending on whether it occurs in coding regions, promotor and regulatory regions, or in selectively neutral DNA such as microsatellites.

For the purpose of this review the term polyphenism is used to describe, in a more narrow sense, the occurrence of intraspecific variation in phenotypes. The focus is specifically on relatively discrete, or discontinuous variation in phenotype expression. Polyphenic mechanisms can be described at two levels: cues that serve as proximate triggers of developmental alternatives, and endogenous response cascades that drive the developmental responses themselves. Triggering stimuli may consist of external environmental factors (e.g., photoperiod, crowding) or internal genetic factors (e.g., alleles at polymorphic loci), or a mixture of the two; endogenous response cascades involve a series of systems that relay, synchonize, and coordinate differentiative processes in target systems.

The most common form of polyphenism in animals is sexual dimorphism. This, in most cases, is triggered by genetic factors that generate distinct phenotypes through a series of mainly endocrine response cascades. Even though sexual polymorphism occurs to some degree in all insects, it is considered only peripherally in this review. Rather, and following the tradition already set in the review on this subject by Hardie and Lees (1985) in the first edition of this series, distinct phenotypes (in either or both sexes) that are triggered by environmental or other exogenous factors are focused. Recent studies on the endogenous response cascades underlying polyphenic trait expression in insects are reviewed, and discuss general properties shared by these mechanisms.

3.13.2. Polyphenism in the Hemimetabola

The most predominant form of polyphenism in hemimetabolous insects is that of wing length. Wing length polyphenism involves differential investment in wings and wing muscles, and appears to reflect an ecophysiological tradeoff in resource allocation between dispersal and reproduction. It is observed in species that colonize and exploit ephemeral resources, in locust and aphid phase polyphenism, and in termite caste polyphenism. In the following sections, the current status of endocrine regulation of wing, phase, and caste polyphenism encountered in the Hemimetabola are reviewed.

3.13.2.1. Hemiptera/Homoptera Wing Polyphenism

3.13.2.1.1. Soapberry bugs A number of hemipteran species have polyphenic mechanisms of wing expression (Tanaka and Wolda, 1987; Dingle and Winchell, 1997). The hemipteran *Jadera haematoloma* (the soapberry bug) exhibits a wing polymorphism with four morphs: two winged forms, one that always has viable flight muscles, and one that histolyzes flight muscles part way through the adult stage, a winged form that never produces viable flight musculature, and a completely wingless form that also produces inviable flight musculature (Dingle and Winchell, 1997). *Jadera haemotoloma* has undergone rapid recent evolution following a host-shift that occurred within the past 50 years (Carroll and Boyd, 1992; Carroll *et al*., 1997, 2001), and one characteristic that has changed dramatically is the proportion of the population expressing wings: derived populations (on the new host) have significantly fewer winged animals than ancestral populations.

Dingle and Winchell (1997) demonstrated that this polyphenism was regulated by a threshold mechanism, and that this threshold behaved like a polygenic character with high levels of additive genetic variance. Manipulations of the amount of nymphal food predictably affected the percent of winged offspring, as did topical applications of the juvenile hormone (JH) mimic methoprene (Dingle and Winchell, 1997). In laboratory animals sampled from an ancestral population, increases in the amount of food decreased the percent developing with wings. Similarly, experimental augmentation of JH levels at the beginning of the final nymphal instar also decreased the proportion of winged animals, suggesting that high levels of JH result in a reduction of the relative amount of wing growth (Dingle and Winchell, 1997).

There is at present no information regarding the sensitivity of animals to JH during the penultimate or earlier instars, nor of the relative levels of ecdysteroids. However, results available at this time show striking similarities with the polyphenic mechanism described below for crickets (see Section 3.13.2.2.1). The timing of the sensitive period, the implicated role for JH, and the direction of the effect of JH, all agree with the basic model for cricket wing polyphenism.

3.13.2.1.2. Planthoppers Planthoppers often occur in both winged and wingless forms (Kisimoto, 1965; Morooka *et al*., 1988; Denno and Perfect, 1994), and dimorphism in these species results from a threshold mechanism with heritable variation for the threshold (Denno *et al*., 1986, 1996; Morooka and Tojo, 1992; Matsumara, 1996; Peterson and Denno, 1997). Where studied, the environmental factor most relevant to wing expression appears to be population density, or crowding, and as with the wing polyphenism already described, the physiological response to nymphal crowding appears to be mediated by levels of JH.

To date, the endocrine regulation of wing polyphenism has been best studied in the brown planthopper, *Nilaparvata lugens* (Homoptera: Delphacidae). The default developmental pathway appears to involve wing production, but Iwanaga and Tojo (1986) showed that both exposure to solitary (low-density) conditions, and topical applications of JH, could suppress wing development and result in a greater proportion of wingless individuals. They identified two sensitive periods, one each in the prepenultimate and penultimate instars (Iwanaga and Tojo, 1986). The timing of these sensitive periods, and the effect of JH, were corroborated by Ayoade *et al*. (1999), who were able to induce wingless morphs in a strain of planthoppers that had been selected to be entirely winged. Bertuso *et al*. (2002) then induced expression of wings in a line selected to be entirely wingless by applying precocene to animals at these same sensitive periods. Precocene disrupts JH synthesis (see **Chapter 3.7**).

Thus, wing polyphenism in planthoppers, as with wing polyphenisms in soapberry bugs and crickets, appears to be regulated by JH during brief sensitive periods late in nymphal life, though in planthoppers the sensitive periods end in the penultimate, rather than the final, nymphal instar. This conclusion has now also received support from JH titer determinations by gas chromatography-mass spectrometry (GC-MS) and a JH binding protein assay (Bertuso *et al*., 2002) showing similar titers between brachypterous and macropterous final instar nymphs. The two morphs then showed divergent titers in the adult stage, where a higher JH titer in the short-winged morph was associated with an earlier development of oocytes (Bertuso *et al*., 2002), thus providing evidence for the dual (developmental and reproductive) role of JH in the divergent life history strategies of planthoppers.

3.13.2.1.3. Aphid phase and caste polyphenism In terms of life cycle complexity, aphids are outstanding champions. Aphid life cycles can include at least two different forms of polyphenism: cyclical switching between asexual reproduction (viviparous parthenogenesis) and sexual reproduction (associated with the production of haploid eggs capable of overwintering after fertilization), and switching between

a wingless sedentary morphology, and a winged morph capable of dispersal. This switching capacity enables aphids to successfully colonize and thrive on highly ephemeral habitats. In some cases these polyphenic switches occur simultaneously (e.g., the switch from asexual to sexual reproduction may coincide with a switch from wingless to winged morphologies), or they may occur separately (the switch from wingless to winged morphologies can occur without coincident changes in mode of reproduction or host-plant preference). The large variation in species-specific aphid life cycles stems from the fact that these elements of polyphenism can be shuffled and integrated as seemingly independent modules in the evolutionary history of each species.

In this review the ontogenetic mechanisms that generate aphid polyphenism is focused (for reviews of aphid life cycles and their ecological significance, see Dixon (1977, 1998) and Moran (1992)). In an effort to facilitate the discussion of aphid polyphenism, and to place these mechanisms in the context of insect polyphenism in general, a simplified description of aphid life cycles is presented and adapt a simplified terminology (Blackman, 1994).

3.13.2.1.3.1. Asexual versus sexual reproduction

All present-day aphids reproduce parthenogenetically, a capacity that appears to have been acquired from a common ancestor some 250 million years ago. Yet only a small number of derived species (i.e., at the tips of the different branches in the phylogenetic tree) are strictly parthenogenetic (Simon *et al*., 2002). Instead, the majority of aphid species facultatively switch between parthenogenetic and sexual modes of reproduction.

During the asexual phase, females give birth to parthenogenetic progeny which develop completely within the ovaries. While these progeny develop, their own ovaries become active, and these embryos begin ovulation before being born. In this extreme telescoping of generations, both daughters and granddaughters develop simultaneously within a single adult female. This parthenogenetic/paedogenetic reproductive strategy of wingless female aphids is unusually efficient for colonizing ephemeral habitats because it can generate large numbers of progeny extremely rapidly. However, rapid production of parthenogenetic daughters can also lead to overcrowding, and with this, the need to disperse to new host plants (see Section 3.13.2.1.3.2).

At the end of a parthenogenetic phase of reproduction, and generally, at the end of the favorable season, female aphids begin producing sexually reproductive offspring. Often, this transition from asexual to sexual reproduction is coupled with a shift from the primary to a secondary host plant species. Aphids that live on a primary host plant with a short seasonal duration may switch to a secondary host plant, and this can occur in two ways, depending on the species. Asexual females may produce a generation of winged daughters that first disperses to the new host plant, and then produces sexually reproductive (male and female) offspring or asexual females may produce winged males and females directly, and these then disperse to the secondary host and reproduce sexually. In either case, the cycle is complete when daughters disperse back to the primary host the following season, and begin parthenogenetic reproduction anew.

As may be expected given the strict seasonality in both host plant alternation and cyclical parthenogenesis, photoperiod appears to be an important environmental cue for this polyphenism. The effects of photoperiod on these key elements in aphid life cycles have long been recognized (review: Hardie and Lees, 1985), and have been studied extensively, especially in the black bean aphid, *Aphis fabae*, and the vetch aphid, *Megoura vicinae* (Hardie, 1981a, 1981b; Hardie and Lees, 1983). The photoperiodic response in the switch from parthenogenetic to sexual forms depends primarily on the length of the scotophase (Hardie *et al*., 1990), and immunocytochemical analyses of opsins and phototransduction proteins suggest that photoperiodic receptors are located in the anterior dorsal region of the aphid protocerebrum (Hardie and Nunes, 2001). In this respect, recent molecular approaches have also been succesful showing that a cDNA encoding a putative amino acid transporter in γ-aminobutyric acid (GABA)-ergic neurons is overexpressed under short-day conditions (Ramos *et al*., 2003).

Once the external trigger (changes in photoperiod, and to a lesser extent, temperature) has been detected, the polyphenic switch between modes of reproduction is coordinated by circulating levels of hormones, in particular JH. Specifically, in *A. fabae,* topical applications of JH inhibit the production of haploid eggs (and, hence, the switch from asexual to sexual reproduction), and promote parthenogenetic development (Hardie, 1981a, 1981b). JH also affected host plant preference behaviors at this same stage (Hardie, 1980, 1981c; Hardie *et al*., 1990), which makes sense, since these events occur simultaneously in *A. fabae*, and since both appear to involve a response to photoperiod. Based on these results, Hardie and Lees (1985) proposed that the endogenous JH titer should be high during long-day conditions, when animals feed on the primary host plant and reproduce parthenogenetically, and low

later in the season, when aphids switch from asexual to sexual reproduction, and from primary to secondary host plants.

3.13.2.1.3.2. Wingless versus winged morphology The switch from wingless to winged morphologies can occur in two different situations. In the first case, parthenogenetically reproducing aphids overcrowd their primary host plant, and must disperse to other (also primary) host individuals. In this case, as conditions become crowded, females begin producing asexual daughters with wings. These winged females disperse to new plants and begin parthenogenetic production of wingless daughters all over again.

At the end of the favorable growing season, however, conditions begin to deteriorate everywhere (e.g., as the primary host plants begin to die). When this occurs, aphids again produce a winged generation of offspring, except that this time the switch between wingless and winged morphologies may coincide with both the switch from primary to secondary host plants, and with the switch from asexual to sexual reproduction. Thus, the first manifestation of the wingless versus winged switch is not associated with a simultaneous switch in the mode of reproduction, but the second one is. This suggests that at least partially independent mechanisms may be involved. Indeed, in some species the winged forms produced at these two times are morphologically distinct (Hille Ris Lambers, 1966), consistent with the idea that separate environmental cues, and/or endocrine mechanisms, may regulate wing expression at these two stages.

Early research on the mechanism of aphid wing polyphenism produced equivocal results, probably due to difficulties distinguishing between hormonally induced "juvenilization" of animals, and polyphenism-specific effects on wing expression *per se* (review: Hardie and Lees, 1985). The complex life cycles of aphids, and the simultaneous involvement of several different forms of polyphenism, made this problem still more difficult. However, several clever experiments with *A. fabae* finally resolved this dilemma, and these clearly establish a role for JH in one form of aphid wing polyphenism (Lees, 1977, 1980; Hardie, 1980, 1981a, 1981b). JH appears to regulate the switch from wingless to winged morphologies that occurs at the end of the growing season (and coincident with the switch from asexual to sexual reproduction). Animals harvested at a stage that would typically begin production of winged offspring (i.e, at the end of the season) could, if exposed to either long days or high temperatures (i.e., summer conditions), be induced to forego wing production and produce wingless daughters instead. This effect of environmental stimuli could be mimicked by topical applications of JH I at this same time, suggesting that high levels of JH are associated with continued production of wingless offspring, and that a seasonal decline in levels of JH may underlie the polyphenic switch from wingless to winged morphologies (as it did with the end-of-season switch between asexual and sexual reproduction).

Interestingly, the most important environmental trigger of wing production is crowding. Animals reared under crowded conditions produce winged progeny irrespective of photoperiod or temperature, and even when exposed to topical applications of JH (Hardie, 1980). These results suggest that the two forms of wing polyphenism are, in fact, regulated by independent endocrine mechanisms. In particular, they suggest that polyphenic production of winged morphologies during the period of parthenogenetic reproduction occurs by a mechanism other than circulating levels of JH, and one that can operate independent of levels of JH (i.e., by a mechanism capable of inducing wing expression even when environmental conditions stimulate high levels of JH).

Major obstacles to direct assessment of JH titers and corpus allatum (CA) activity in aphids are their small size and telescoping of generations. Chemical allatectomy by precocenes turned out to be a valuable research tool in this context, even though not all aphid species are equally susceptible (Hardie, 1986), and not all precocene compounds acted in the same direction (Hardie *et al.*, 1995, 1996). JH rescue experiments on precocene-treated larvae of a pink pea aphid, *Acyrthosiphon pisum* clone (Gao and Hardie, 1996) showed that the destruction of the CA by precocene-II or precocene-III resulted in precocious adult development. The alate-promoting property of these compounds appeared to be unrelated to the decreased JH titer, and instead depended heavily on population density (Hardie *et al.*, 1995). In contrast, flight muscle breakdown in alate adult *A. pisum*, that had undertaken a migratory flight to a new host plant, has been shown to be under JH control (Kobayashi and Ishikawa, 1993, 1994).

Consistent with the notion that genetic variation must underly differing response thresholds to environmental cues, a single locus on the X chromosome has recently been demonstrated to affect the propensity for winged male production in different, coexisting clones of *A. pisum* (Cauillaud *et al.*, 2002). And precocene treatment, in contrast, was much more effective in apterizing presumptive alate

females than males in this species (Christiansen-Weniger and Hardie, 2000).

Interestingly, apterization of presumptive alates can also occur as a consequence of parasitization during the early larval instars (Johnson, 1959). Parasitization effects on wing development appear to be regulated relatively independent of metamorphosis, and in particular, seem to occur independent of JH (Hardie and Lees, 1985). In pea aphids, parasitization by *Aphidius pisum* caused apterization and other correlated changes in body shape (Christiansen-Weniger and Hardie, 2000), yet parasitization of the same species by *A. ervi* had the opposite effect, resulting in a higher proportion of winged offspring (Sloggett and Weisser, 2002). The developmental mechanisms underlying the divergent responses to parasitization are not yet understood.

3.13.2.1.3.3. Soldier aphids It is worth noting that aphids, the masters of polyphenism, exhibit yet another form of polyphenism. Some aphid species facultatively produce a behaviorally and morphologically distinct soldier caste. Since its original description (Aoki, 1977), this phenomenon has been detected in over 50 aphid species in the families Pemphigidae and Hormaphididae (Stern *et al.*, 1997). To date, most studies of aphid soldiers have focused on clonal relatedness and kin selection (Carlin *et al.*, 1994; Abbot *et al.*, 2001), as well as colony division of labor and defense against predators (Schutze and Maschwitz, 1991; Foster and Rhoden, 1998; Rhoden and Foster, 2002). Little is known about proximate mechanisms that induce soldier formation, except for a positive correlation between soldier proportion and colony size (Ito *et al.*, 1995), and the fact that, ontogenetically, the development of a soldier morphology appears to be linked to the replacement of the reproductive system by fat body cells and the lack of endosymbionts (Fukatsu and Ishikawa, 1992).

In conclusion, the mechanisms of endocrine control in aphid phase polyphenism are still far from resolved. In fact, there seem to be more questions than answers. It now appears that the existing grouping of aphid polyphenic mechanisms may be biologically misleading. Wing polyphenism occurs at two different stages in the annual life cycle of aphids. On the surface, these two switch mechanisms appear to be similar – even one and the same. Yet, they are regulated in response to different environmental cues, and they involve completely different endocrine mechanisms. Thus, wing polyphenism represents not one, but two developmental mechanisms. Again, on the surface, reproductive polyphenism would appear to be very different from wing polyphenism. Yet reproductive polyphenism occurs at the same time as one of the wing polyphenisms, occurs in response to the same environmental stimuli, and is regulated in the same direction by the same hormone (JH) (**Figure 1**). Thus, a more useful description of aphid polyphenism may involve a new classification scheme: an "autumn" polyphenism that includes both wing morphology and mode of reproduction, and which is regulated by a seasonal change in photoperiod and a corresponding decline in levels of JH, and a "summer" polyphenism that only involves wing expression, that occurs in response to changes in crowding, and that incorporates an as-yet unidentified endocrine mechanism that operates independently from circulating levels of JH.

3.13.2.2. Orthoptera

3.13.2.2.1. Wing polyphenism in crickets Facultative dispersal strategies in crickets involve the relative amounts of growth of the wings and associated wing musculature. Animals can have full-size, functional wings (macropters), miniature wings (micropters), or be entirely wingless (brachypters). Differences in wing expression (and associated flight capability) may occur among species (e.g., Harrison, 1980), among populations of a single species (e.g., Harrison, 1979), or even among time periods within a single individual's lifetime (e.g., some crickets shed their wings and histolyze flight muscles after mating (Srihari *et al.*, 1975)).

In a number of cricket species, wing expression is facultative, and depends on environmental conditions encountered during nymphal development, such as temperature (Ghouri and McFarlane, 1958; McFarlane, 1962), photoperiod (Masaki and Oyama, 1963; Saeki, 1966a; Alexander, 1968; Mathad and McFarlane, 1968; Tanaka *et al.*, 1976), diet (McFarlane, 1962), and population density (Fuzeau-Braesch, 1961; Saeki, 1966b; Zera and Tiebel, 1988; Zera and Denno, 1997). In these taxa, wing expression appears to be regulated by a threshold mechanism, and population comparison, controlled-breeding, and artificial selection studies all suggest high levels of additive genetic variation for the threshold of this polyphenism (Harrison, 1979; Roff, 1986, 1990; Fairbairn and Yadlowski, 1997).

The physiology of wing polyphenism has been most thoroughly studied in *Gryllus rubens* (Orthoptera: Gryllidae). Wing expression in this species is sensitive to population density; in particular, the level of crowding experienced by nymphs as they develop (Zera and Tiebel, 1988). Experiments that transferred animals between experimentally staged high and low

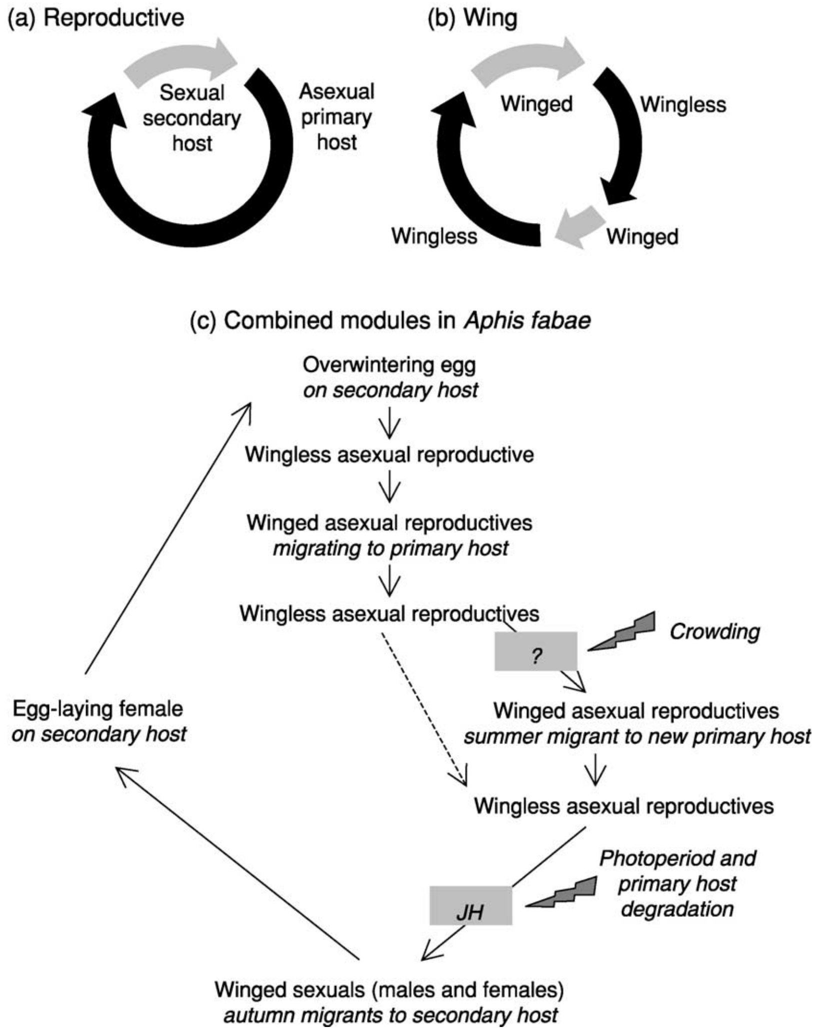

Figure 1 Polyphenism in aphid life cycles. Traditional classifications of aphid polyphenism group these mechanisms into two modules. (a) Module 1 is a switch in reproductive mode, sometimes associated with a switch from a primary to a secondary host plant. (b) Module 2 represents the switch from a wingless to a winged form. However, wing polyphenism includes two distinct events that occur at different periods of the aphid life cycle, and that incorporate different endocrine mechanisms, only one of which involves JH. (c) The modular combination is exemplified in the beam aphid, *Aphis fabae*, showing three switches from wingless to winged in the annual cycle. The first one occurs when wingless (parthenogenetic) females that arose from overwintered eggs produce winged (parthenogenetic) daughters that migrate to the primary host. The mechanisms underlying this switch are little understood. As a large population of wingless (parthenogenetic) females builds up on this host and crowding reaches critical levels, some winged (parthenogenetic) females are produced that colonize new primary hosts to initiate a new cycle of wingless generations. This switch in wing morphs does not involve a switch in reproductive mode and occurs independent of JH levels. It represents a JH-independent ''summer'' polyphenism (bottom gray arrow in b). The third switch from a wingless to a winged morph occurs at the end of the favorable season when primary host plants degrade. This is now also a switch in reproductive mode and a move of mated females to a secondary host plant where they either produce overwintering eggs or another generation of egg-laying females. This third switch in wing expression is controlled by photoperiod, resulting in decreased JH titers that allow growth of the wing anlagen. It represents the JH-dependent ''autumn'' polyphenism (top gray arrow in b). Graph compiled from data by Hardie, J., Lees, A.D., **1985**. Endocrine control of polymorphism and polyphenism. In: Kerkut, G.A., Gilbert, L.I. (Eds.), Comprehensive Insect Physiology, Biochemistry and Pharmacology, vol. 8. Pergamon, Oxford, pp. 441–489; Hardie, J., Mallory, A.C.L., Quashiewilliams, C.A., **1990**. Juvenile hormone and host plant colonization by the black bean aphid, *Aphis fabae*. *Physiol. Entomol. 15*, 331–336; and Hardie, J., Gao, N., Timar, T., Sebok, P., Honda, K., **1996**. Precocene derivatives and aphid morphogenesis. *Arch. Insect Biochem. Physiol. 32*, 493–501.

densities revealed two sensitive periods relevant to expression of wings: during the middle of the penultimate and final nymphal instars, respectively (Zera and Tiebel, 1988). The default developmental pattern appeared to be winged, but animals could be switched to a wingless fate if they were exposed to crowded conditions during either or both of these sensitive periods (Zera and Tiebel, 1988).

This developmental response to nymphal crowding could be mimicked by the topical application of either JH III, or methoprene, during these same two critical periods: augmented levels of JH reduced the relative amount of wing growth (Zera and Tiebel, 1988). This suggested that titer differences of JH might underlie wing polyphenism. These presumed titer differences were corroborated by direct measures of JH titers in presumptive winged and wingless animals (Zera *et al*., 1989). In addition, a second titer difference was observed. Animals destined to produce wings had higher levels of ecdysteroids than animals destined not to produce wings (Zera *et al*., 1989).

Subsequent experiments have refined this basic model considerably. Zera and Tobe (1990) compared rates of JH biosynthesis in presumptive winged and wingless animals, and found no differences, suggesting that morph-specific variation in levels of JH result from differential clearance of JH from the blood, rather than from differential rates of hormone biosynthesis (see **Chapter 3.7**). Zera and Tiebel (1989) demonstrated that degradation of JH in *G. rubens* is primarily due to the enzyme juvenile hormone esterase (JHE), and they found higher levels of JHE in winged animals than in wingless animals. Titer differences in JHE were accompanied by corresponding differences in rates of JH clearance from hemolymph *in vivo* (Zera and Holtmeier, 1992). Finally, the timing of these morph-specific differences in levels of JHE coincided with the two sensitive periods already described, and with the observed morph-specific differences in JH titer.

Based on these results, Zera has proposed the following model (after Zera and Holtmeier (1992) and Zera and Denno (1997)). Crickets have two sensitive periods, occurring during the middle of the penultimate and final nymphal instars. During these periods, wing development is sensitive to external environmental factors (crowding), and these external stimuli appear to result in morph-specific differences in levels of two hormones: JH and 20-hydroxyecdysone (20E). Animals destined to produce wings have lower levels of JH, and higher levels of ecdysteroids, than animals destined to mature without wings (**Figure 2**). Morph-specific differences in levels of JH appear to result from subtle differences in the timing of the decline in JH titers during these sensitive periods, and these differences in JH titers result from winged animals having higher levels of the degradative enzyme JHE than wingless animals. Thus the default pattern of development entails production of wings, but a subset of individuals (animals with levels of JH above a genetically mediated threshold level) experience a delay in the rise in levels of ecdysteroids, and low levels of ecysteroids during the sensitive period probably “reprograms” these individuals towards production of a wingless body form.

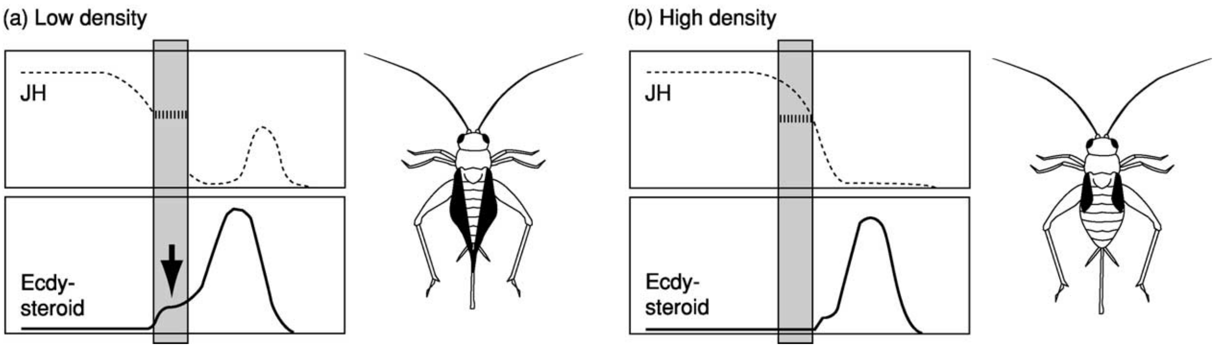

Figure 2 Facultative wing-length polyphenism in the cricket *Gryllus rubens* is a response to environmental conditions, especially nymphal crowding, and is controlled by a hormonal threshold mechanism acting during critical periods (shaded bars) in the two final instars of postembryonic development. At low population densities, the JH titer drops below a critical threshold level due to enhanced JH esterase activity, whereas the premolt ecdysteroid titer exceeds a threshold level. This endocrine situation permits wing development to a macropterous phenotype. In contrast, high population densities lead to an above-threshold JH titer and a low ecdysteroid titer during this critical period. Consequently, wing development is inhibited and brachypterous adults are formed. Graph compiled from data and models by Zera, A.J., Tiebel, K.C., **1988**. Brachypterizing effect of group rearing, juvenile hormone III and methoprene in the wing-dimorphic cricket, *Gryllus rubens. J. Insect Physiol. 34*, 489–498; Zera, A.J., Holtmeier, C.L., **1992**. *In vivo* and *in vitro* degradation of juvenile hormone-III in presumtive long-winged and short-winged *Gryllus rubens. J. Insect Physiol. 38*, 61–74; and Zera, A.J., Denno, R.F., **1997**. Physiology and ecology of dispersal polymorphism in insects. *Annu. Rev. Entomol. 42*, 207–230.

A genetic background for threshold mechanisms in wing dimorphic gryllids has been established for *Gryllus firmus* and now serves as a model system to investigate functional causes of adult life history evolution. In a fusion of resource allocation studies and metabolic biochemistry, Zhao and Zera (2002) and Zera and Zhao (2003) demonstrated a genetic bias for flight-fuel synthesis (mainly triglycerides) in the flight-capable genotype versus a bias for ovarian lipids (phospholipids) in the flightless one. When JH was applied topically the adult flight-capable morph shifted its lipid metabolism towards that of the flightless morph.

3.13.2.2.2. Phase polyphenism in locusts Locust phase polyphenism (a switch between solitary and gregarious forms) has dramatically impacted human history. The gregarization phenomenon can lead to staggering densities of animals, and these migratory swarms of locusts are one of the world's most devastating plagues. On the other hand, their capacity to switch between solitary and gregarious forms constitutes a remarkable developmental feat that has facilitated study of the hormonal control of complex animal life cycles. This polyphenism is common in several species of locusts, but is most clearly expressed in the migratory locust (*Locusta migratoria*), the desert locust (*Schistocerca gregaria*), and the red (*Nomadacris septemfasciata*) and brown (*Locustana pardalina*) locusts of Africa.

Phase polyphenism is a complex phenomenon that involves changes in body coloration, wing morphology, reproductive physiology, energy metabolism, and behavior (Uvarov, 1921). "Solitary" phase animals generally avoid conspecifics, and have cryptic, green color patterns, and reduced wing morphologies and musculature, whereas "gregarious" phase animals aggregate – actively seek conspecifics – and have a dark background pigmentation with yellow or orange color pattern, and more fully developed wings and wing musculature. The complexity of this syndrome sets locust phase polyphenism apart from the apparently simpler wing polyphenisms already discussed for other hemimetabolans (including other orthopterans). Studies comparing patterns of protein and gene expression between solitary and gregarious animals reveal numerous and complicated differences between the forms (Wedekind-Hirschberger *et al*., 1999; Clynen *et al*., 2002; Rahman *et al*., 2003), again reflecting the diversity of characters involved in this polyphenism. Perhaps the most important difference between locust phase polyphenism and the other polyphenisms discussed so far is that the switch between solitary and gregarious forms takes longer: the full transition requires multiple generations.

Gradual phase transition from solitary to gregarious locust forms was one of the earliest of the studied polyphenisms (e.g., Uvarov, 1921), and it has been clear for decades that the endocrine system, and in particular, JH, was involved (Joly, 1954; Staal and de Wilde, 1962; Couillaud *et al*., 1987). However, results from many of these early hormone studies were equivocal, and for some time the role of JH has been controversial (Pener, 1991; Applebaum *et al*., 1997; Pener and Yerushalmi, 1998; Dorn *et al*., 2000). The gradual, multigeneration nature of the response has compounded this problem in two ways. First, it has made interpretation of results and comparison across studies difficult, because not all of the involved traits respond at the same time. Some, like color, change rapidly, while others, like full migratory behavior, require much longer – often several generations. Second, the gradual nature of this phase transition meant that wild-caught, fully gregarious animals were not the same morphologically, physiologically, or behaviorally, as "gregarious" animals raised from one generation of rearing under crowded conditions in the laboratory. Yet, as pointed out by Dorn *et al*. (2000), these terms were used interchangeably, leading to confusion in the search for general patterns. Fortunately, an impressive series of recent studies has brought resolution to some of these apparent discrepancies.

3.13.2.2.2.1. Changes in color and wing morphology Changes in locust color may be triggered by a variety of environmental cues (e.g., humidity; Dorn *et al*. (2000)), but one important cue is the level of crowding experienced by nymphs as they develop. Exposure to crowded conditions induces a shift from the solitary (green) to the gregarious (black with yellow (*S. gregaria*) or orange (*L. migratoria*)) form, and much of this shift appears to be mediated by hormones. Several recent studies suggest that the neurohormone *Locusta migratoria* dark color-inducing neurohormone (Lom-DCIN) (now chemically characterized as [His^7]-corazonin) induces the expression of the black pigmentation and "foreground" color patterns typical of the gregarious form (Pener *et al*., 1992; Tanaka and Pener, 1994; Tanaka, 2000a, 2000b, 2000c, 2001). Controlled application experiments showed that increases in [His^7]-corazonin levels could switch animals from a solitary to a gregarious color pattern (Tanaka, 2000c, 2001). Juvenile hormone also affects locust color, but these effects occur independent from, and in the opposite direction to, the effects of [His^7]-corazonin.

Average levels of JH regulate the darkness of the "background" pattern (Tanaka, 2000a, 2001): higher levels of JH are associated with greener backgrounds, and hence a more solitary morphology, whereas the darker gregarious background pigmentation is associated with low levels of JH.

It is now recognized that the solitary–gregarious phase transition is associated with changes in a suite of additional morphological traits, including aspects of wing morphology and relative wing size. Recent multivariate morphometric studies found clear morphological separation of solitary and gregarious forms (Dorn *et al.*, 2000). Topical applications of a JH analog (JHA) to gregarious locust nymphs (*S. gregaria* and *L. migratoria*) caused many – but not all – of these morphological characters to shift towards "solitary" values by the time animals reached the adult molt (Dorn *et al.*, 2000). Interestingly, these "solitary" animals (i.e., animals reared under crowded conditions, but exposed to topical applications of JHA) also resembled juvenile animals. Specifically, they were morphological intermediates between fifth instar nymphs and adults reared under crowded conditions (Dorn *et al.*, 2000). However, unlike the situation with aphids, this "juvenilization" effect of JHA does not appear to be an artifact. Solitary animals normally resemble "juvenile" versions of the gregarious form, and "juvenilization" and "solitarization" may be overlapping concepts with respect to some traits (Dorn *et al.*, 2000).

Application of the neurohormone [His[7]]-corazonin also affected these morphological characteristics (in addition to the effect on color already discussed), and again, these effects occurred in the opposite direction to those induced by JH. Injections of [His[7]]-corazonin shifted animals from a solitary towards a gregarious morphology (Tanaka *et al.*, 2002).

3.13.2.2.2.2. Hormone titers of solitary and gregarious nymphs In a pioneering study of CA activity, Injeyan and Tobe (1981) showed that during the fourth nymphal instar, CA were more active in animals reared under isolated conditions than they were in animals reared under crowded conditions. More recently, Botens *et al.* (1997) measured JH III titers in laboratory animals reared under these same (isolated and crowded) conditions, and they identified a critical period during the middle of the fourth (penultimate) nymphal instar when solitary and gregarious animals differed in their level of JH. Juvenile hormone levels dropped sooner in gregarious animals (Botens *et al.*, 1997), so that during this critical window, gregarious animals had lower levels of JH than solitary animals (**Figure 3**).

Furthermore, when animals reared for three instars under isolated conditions were transferred to crowded conditions (at the beginning of the fourth instar), their JH titers decreased within 3 days to levels detected in nymphs reared entirely under crowded conditions (Botens *et al.*, 1997). Precisely the opposite effect (i.e., an increase in JH) occurred when animals were moved from crowded to isolated conditions. Finally, Botens *et al.* (1997) measured JH III titers for wild-caught solitary and

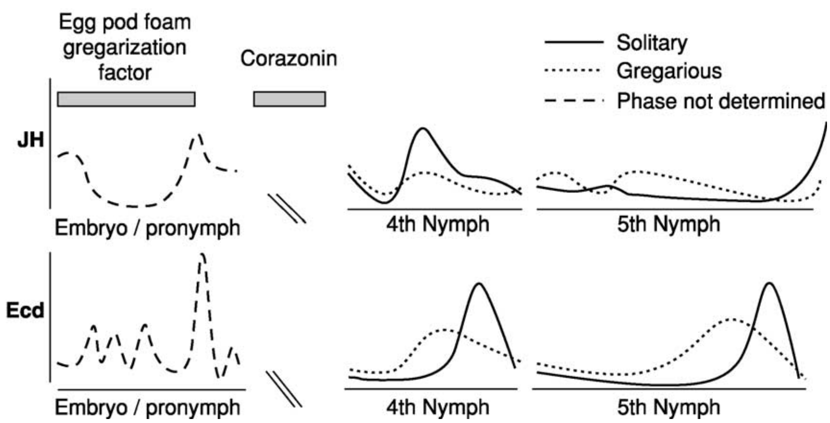

Figure 3 Juvenile hormone and ecdysteroid titers during embryonic and postembryonic development of solitary and gregarious morphs of migratory locusts (*Locusta migratoria* and *Schistocerca gregaria*). Hormone titers during embryonic development were determined by Lageux *et al.* (1977) and were not specified with respect to phase. The ecdysteroid titer peaks during embryonic development are associated with embryonic molts and the JH-free period in the middle of embryonic development is required for correct blastokinesis (Truman and Riddiford, 1999). Larval hormone titers were determined by Botens *et al.* (1997), Tawfik *et al.* (1997a), and Tawfik and Sehnal (2003). Juvenile hormone application to gregarious/crowded fourth instar larvae was shown to shift several, but not the entire complex of solitary characters (see text). Corazonin application to isolated/solitary second and third instar larvae induces the gregarious-phase foreground coloration (Tanaka, 2000a, 2000b, 2000c). Exposure of eggs of isolated/solitary females to extracts egg pod foam from gregarious/crowded females shifts offspring to the gregarious phase (Hägele *et al.*, 2000).

gregarious animals, and found the same result: JH titers during the middle of the fourth nymphal instar were higher in solitary animals than in gregarious animals. Thus, it appears that circulating levels of JH may underlie at least part of the physiological response to nymphal crowding.

Solitary and gregarious locusts also differ in their 20E levels (**Figure 3**). Animals reared under crowded conditions have a lower but more prolonged premolting ecdysteroid peak than animals reared under solitary conditions (Tawfik *et al.*, 1996; Tawfik and Sehnal, 2003) in the penultimate and last nymphal instar. These differences in ecdysteroids coincide with the phase-specifically modulated JH titer, suggesting a synergistic interaction of these major morphogenetic hormones in establishing the expression of a set of divergent phase characters, particularly during the critical penultimate instar.

Clearly, expression of multiple characters is affected by crowding, and multiple hormones appear to be involved. Although JH and ecdysone likely coordinate much of at least the more rapid shifts in locust form, other factors like the neurohormone [His^7]-corazonin are involved as well. There may even be multiple forms of JH in locusts, each with effects on specific subsets of the suite of phase-related traits. Darrouzet *et al.* (1997) recently found that the CA of *L. migratoria* synthesize two hydroxy-juvenile hormones (12′-OH JH III and 8′-OH JH III) in addition to JH III. These products have not been detected by the standard radiochemical assays (e.g., Tobe and Pratt (1974)), and whether these are secreted into the hemolymph, or whether they affect phase polyphenism, remains to be explored.

3.13.2.2.2.3. Changes in adult behavior and physiology Solitary and gregarious adult locusts differ in behavior and physiology, as well as morphology. For example, gregarious animals show an affinity for other locusts (aggregative behavior), and a strong propensity for migratory flight, in contrast with solitary animals. These behavioral differences are accompanied by corresponding differences in adult physiology related to the two different life-history strategies. Phase differences are noticable in the strength of the adipokinetic reaction which mobilizes fat body lipids during long distance flight (Ayali and Pener, 1992; Chino *et al.*, 1992; Schneider and Dorn, 1994; Ogoyi *et al.*, 1996), and in the onset of egg production (solitary females generally begin egg production earlier than gregarious females).

As with the morphological differences already discussed, behavioral differences between solitary and gregarious forms also appear to be driven – at least in part – by hormones, except that in this case, the relevant endocrine differences between morphs are observed after animals are adults (rather than during nymphal instars). In adult females, both solitary and gregarious animals show a large increase in JH levels within the first 2 weeks post eclosion (Dale and Tobe, 1986; Tawfik *et al.*, 2000). However, this rise in JH occurs earlier in solitary females than it does in gregarious females (Dale and Tobe, 1986; Tawfik *et al.*, 2000). Similar differences in the timing of hormone secretion were observed for ecdysteroids: ecdysone levels rose earlier in solitary females than in gregarious ones (Tawfik *et al.*, 1997a, 1997b; Tawfik and Sehnal, 2003).

These differences in the timing of adult female JH and ecdysteroid release correspond precisely with phase-specific differences in the timing of the first oogenesis cycle (**Figure 4**); females raised under isolated conditions begin producing eggs sooner than females reared under crowded conditions (Tawfik *et al.*, 1997a, 1997b, 2000). These same hormone titer differences also correspond with migratory flight fuel metabolism, but in the opposite direction (Wiesel *et al.*, 1996). Low levels of JH (as in gregarious females) stimulate utilization of stored lipids for flight, whereas high levels of JH (as in solitary females) reduce this use, and instead result in vitellogenin synthesis and lipid allocation to oocytes (Wiesel *et al.*, 1996; see **Chapter 3.9**). Thus, hormones appear to underlie a fundamental difference in patterns of stored-resource allocation between solitary and gregarious adult females, with these resources being directly allocated to eggs in solitary animals, but delayed and first used for migratory flight in gregarious animals.

In adult males, the principal behavioral difference between solitary and gregarious phase individuals involves production and secretion of phenylacetonitrile, the main component of the aggregation pheromone (Njagi *et al.*, 1996) (see **Chapter 3.14**) and this also appears to be regulated by phase-specific titer differences in hormones. As with females, solitary and gregarious male locusts differ in their JH and ecdysteroid titers (**Figure 4**). In particular, during a critical sensitive period approximately 15 days post eclosion, animals reared under isolated conditions have lower levels of JH, and higher levels of 20E, than animals reared under crowded conditions (Tawfik *et al.*, 1997a, 1997b, 2000). Synthesis of phenylacetonitrile is stimulated by high levels of JH, and inhibited by high levels of 20E, and this results in high levels of pheromone production in gregarious (but not solitary) animals (Tawfik *et al.*, 1997a, 1997b, 2000).

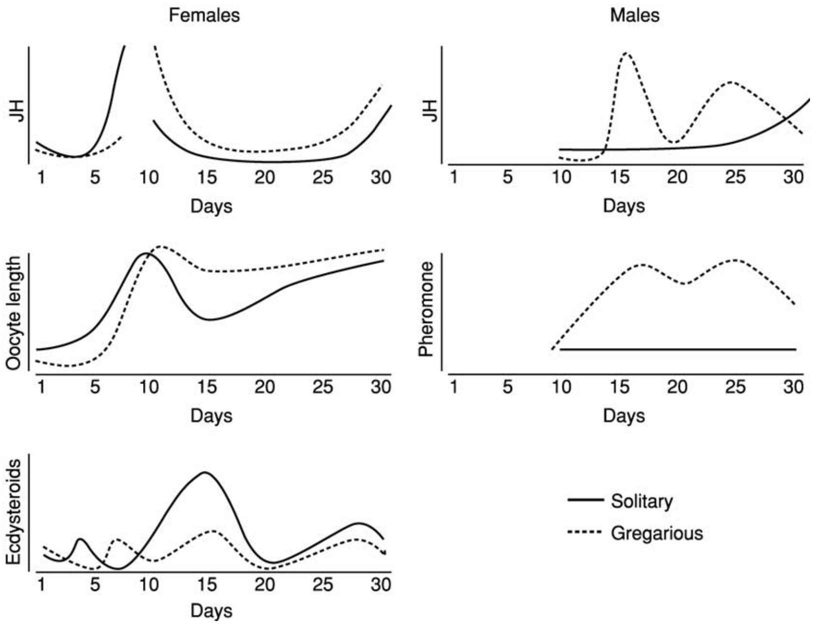

Figure 4 Hormone titers in relation to terminal oocyte length in solitary and gregarious-phase locust females (*Locusta migratoria* and *Schistocerca gregaria*), and the phase relationship between JH titer and pheromone production (phenylacetonitrile) in adult males. The first oogenic cycle is slightly advanced in solitary females, and is probably elicited by the earlier increase in JH titer and the advanced ecdysteroid titer peak. In gregarious-phase males, the sharp increase in JH titer between days 10 and 15 correlates with a strongly enhanced production of a gregarization pheromone. Graph compiled from data by Tawfik, A.I., Osir, E.O., Hassanali, A., Ismail, S.H., **1997a**. (Ed.), Progress in Developmental Endocrinology, vol. X, part B. John Wiley, Chichester, pp. 205–253.

3.13.2.2.2.4. Maternal effects on offspring development Interestingly, female locusts transfer ecdysteroids to their eggs. High levels of ecdysteroids have been found in vitellogenic ovaries (Lageux *et al.*, 1977), and may, in fact, be synthesized there. These ecdysteroids are transferred to the developing eggs and together with JH appear to affect molting events during embryonic development (Lageux *et al.*, 1979; Truman and Riddiford, 1999) (**Figure 3**).

Tawfik *et al.* (1999) and Tawfik and Sehnal (2003) found that the ecdysteroid content of *S. gregaria* ovaries in females reared under crowded conditions were up to four times higher than those in the ovaries of females reared in isolation (8.9 ng mg^{-1} versus 2.3 ng mg^{-1} tissue before egg-laying), and these phase-specific differences in egg ecdysteroid levels persisted after the eggs were laid (89 ng versus 14 ng per egg), and even into newly hatched larvae (Tawfik *et al.*, 1999). These studies raise the exciting possibility that endocrine differences in the mothers (resulting from their exposure to crowding as they developed) are carried over to their offspring – and this may help explain some aspects of the multigenerational nature of this phase transition.

Pheromones and semiochemicals transferred to eggs also may direct embryonic development. These compounds, when coated on the eggs, attract other gravid females to the area and result in clustered oviposition (Saini *et al.*, 1995), but they also lead to increases in the expression of "gregarious" characteristics in offspring. Washing freshly laid eggs from gregarious females shifts phase characteristics from gregarious towards solitary forms, and application of female accessory gland products to these washed eggs restores expression of the gregarious characters (McCaffery *et al.*, 1998; Hägele *et al.*, 2000).

Thus, there are several ways in which maternal compounds can direct the development of embryos and early instar animals. Expression of offspring traits may be influenced by differences in the levels

of maternally deposited egg steroids, and/or levels of maternally deposited semiochemicals and pheromones, and all of these may contribute to the multigenerational aspects of this remarkable insect polyphenism.

3.13.2.3. Isoptera (Termites): Caste Polyphenism in the Hemimetabola

The characterization of termites as "social cockroaches" suggests a very special postion of termites within insects expressing caste polyphenism. Caste polyphenism in termites differs from that of the holometabolous Hymenoptera in three very important ways. First, all isopteran species are social, whereas sociality has evolved in only a few branches of the Hymenoptera. Second, caste polyphenism in termites is a larval polyphenism – i.e., it affects primarily the morphologies and behavior of larvae, rather than adults. Finally, in termite societies both males and females form castes and, thus, contribute equally to the social organization (hymenopteran societies are female).

Hemimetabolous development permits postembryonic stages to participate actively in termite colony life, and these postembryonic larval and nymphal stages, in fact, constitute the major workforce of termite colonies (in termites, early postembryonic instars are usually called "larvae," whereas later instars are called "nymphs"; for simplicity, all postembryonic termite instars are referred to as larvae). In general, the only imagos encountered in a termite colony are the sexuals (primary reproductives (king and queen) and, at certain times of year, the predispersal sexual alates). In the adults, there is little visible dimorphism between the sexes, and the differences that exist result from the high degree of physogastry of the egg-laying queen (Bordereau, 1971). In contrast, many termites exhibit marked sexual dimorphism in the larval stages, especially in taxa that show a sex bias with respect to caste phenotypes. For termite sociality, the limelight is thus on the polyphenism exhibited by the larval stages.

Larval polyphenism means that in subsequent developmental stages, an individual can progressively specialize for different colony tasks ("temporal polyphenism" according to Noirot and Bordereau (1991)). As such, caste polyphenism is tightly linked to the molting process, and to the endocrine factors regulating molting. Interestingly, molting in termites is no longer necessarily connected with larval growth (Noirot, 1989), and larval molting has instead been co-opted as a mechanism for polyphenic changes in animal shape.

Recent reviews of termite societies and on trajectories of caste development within these (Noirot, 1985a, 1985b, 1985c, 1989; Noirot and Pasteels, 1987; Roisin, 2000) emphasize a distinction between caste systems (and polyphenic mechanisms) of "lower" (Mastotermitidae, Kalotermitidae, Hodotermitidae, and Rhinotermitidae) and "higher" termites (Termitidae). These groups differ primarily in the development of the worker caste. In the higher termites, workers represent a clear developmental trajectory, and a terminal molt. In contrast, in the lower termites, a true worker caste does not exist. Instead, most of the larval stages perform worker functions (i.e., colony maintenance). As such, workers in the lower termites do not undergo a terminal molt, and these individuals retain the capacity to develop subsequently into either soldiers or reproductives. In the lower termites, these late-instar larvae that comprise the major workforce of a colony are generally described as pseudergates.

Caste polyphenism in the termites involves several possible developmental switches (e.g., larva to pre-reproductive (with wingpads) to reproductive, larva to presoldier to soldier, and, in the higher termites, larva to worker). These developmental transformations may require several subsequent molts, and several different critical periods (**Figure 5**). Several of these developmental transformations can be reversed midway through the process, permitting extraordinarily flexible adjustment of the production of castes in the regulation of colony structure (this is particularly common in the lower termites, which are famous for undergoing stationary, and even regressive molts). Here, studies examining larva to reproductive, and larva to soldier polyphenisms are reviewed. Larva to worker development has yet barely been explored.

3.13.2.3.1. Larva to reproductive polyphenism Termite larvae occasionally molt into reproductives. The most commonly encountered reproductives are the alates – the winged males and females that disperse from termite colonies to breed and find new colonies. After mating, each new royal pair sheds its wings and finds a colony. A second type of reproductive consists of a replacement king or queen within an existing colony. When colonies bud, or when one of the original pair dies, replacement reproductives can be produced. In either case (dispersing alates or replacement reproductives), early commitment towards a sexual fate is first evidenced by the appearance of rudimentary wingpads, which may appear several molts before the terminal, adult molt. However, in the developmental trajectory of "replacement" reproductives, these wingpads fail to fully develop (replacement kings or queens do not have functional wings). Termites that do not develop

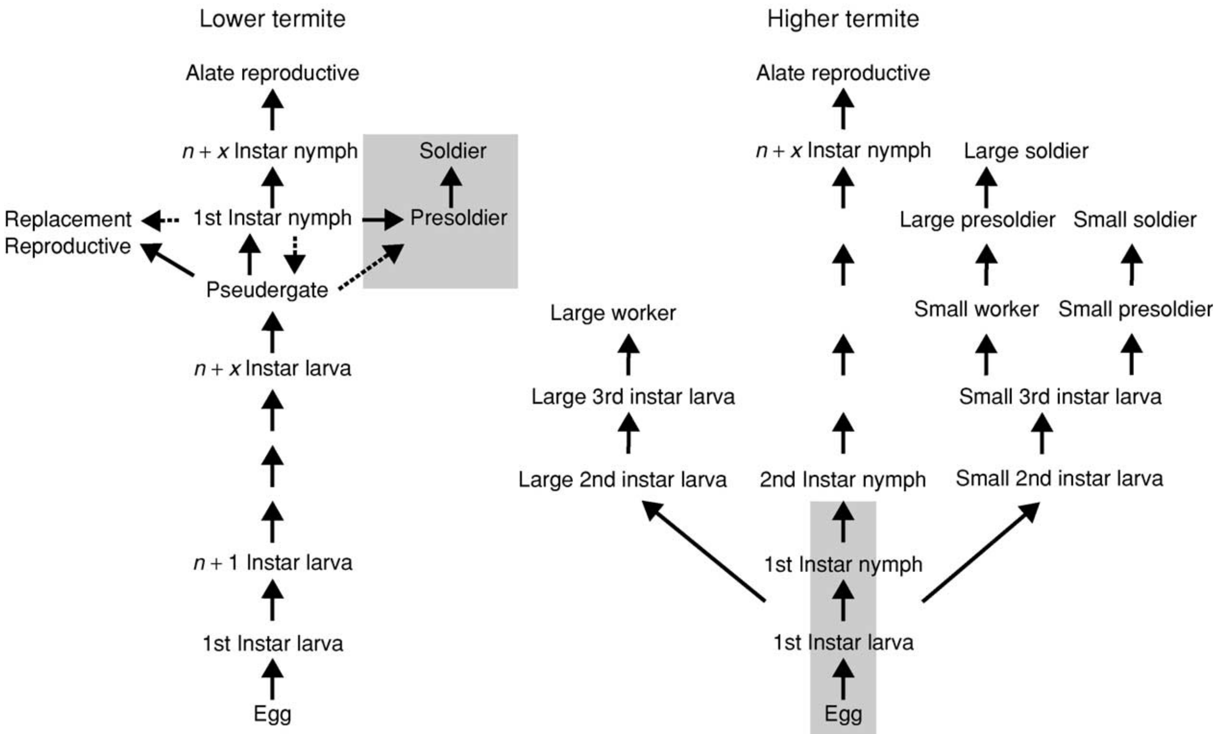

Figure 5 Generalized developmental pathways in lower and higher termites. In termite studies it is customary to denote all immatures stages without wingpads as larvae. Nymphs are stages exhibiting wingpads, and thus are potentially developing into sexual alates. Lower termites pass through a variable number of larval stages before the pseudergate stage which is the main branching point for nymphal to alate sexual (imaginal) development, to neotenic replacement reproductives, or to soldiers. There is no definitive worker caste since tasks of colony maintenance are performed by larvae. In higher termites, the branch point for developmental pathways is set early in larval development, leading alternatively to the nymphal/adult line, the soldier line, and to a definitive worker caste. Shading emphasizes points where hormone titers (JH and/or ecdysteroids) differ between castes, or where JH applications bias development, principally into presoldier/soldier differentiation. (Modified from Noirot, C., **1990**. Sexual castes and reproductive strategies in termites. In: Engels, W. (Ed.), Social Insects: An Evolutionary Approach to Castes and Reproduction. Springer-Verlag, Heidelberg, pp. 5–35; Hartfelder, K., **2000**. Arthropoda – Insecta: caste differentiation. In: Dorn, A. (Ed.), Progress in Developmental Endocrinology, vol. X, part B. John Wiley, Chichester, pp. 185–204; and Miura, T., **2001**. Morphogenesis and gene expression in the soldier-caste differentiation of termites. *Insectes Sociaux 48*, 216–223.)

wingpads during any of these decisive molts are committed to becoming either workers or soldiers.

Interestingly, the number of larval instars that an individual completes prior to committing to a reproductive or a neuter (worker or soldier) differs considerably among species. In the higher termites, this decision usually occurs during the first or second instar, while lower termites may pass through six or more precommitment molts (**Figure 5**). The general evolutionary trend appears to involve a gradual diminution of the uncommitted larval instars.

Environmental triggers of termite reproductive caste development primarily involve demographic aspects of the colony itself, as communicated through chemical signals transmitted from workers to larvae (i.e., pheromones (Noirot, 1990)). In fact, the term "pheromone" was derived from early studies of chemical communication in termites (Karlson and Lüscher, 1959). Most early work on this polyphenism focused on the differentiation of *Kalotermes flavicollis* larvae after removal of the primary reproductive pair (e.g., Lüscher, 1964; review: Wilson, 1971). Once the king or queen had been removed, larvae began developing into replacement reproductives, suggesting that levels of chemical signals from the primary pair triggered the switch between nonreproductive and reproductive development. These studies led to the now classic model of negative feedback, whereby the king and queen each secrete compounds that repress the development of replacement reproductives of their respective sex (Lüscher, 1964), possibly via the neuroendocrine system (Lüscher, 1976).

However, recent critical revision has called this classic model into question (Pasteels and Roisin, 2001), and it is now clear that if it does apply, it does so only in the lower termites. There is little evidence for pheromonal inhibition of reproductive development in the higher termites, where this developmental option is extremely rare, and

restricted to only one or a few early larval instars (Noirot, 1990).

In addition, termite colonies annually produce large numbers of winged reproductives in the presence of the king and queen (and presumably in the presence of their pheromonal secretions). Large numbers of these "alates" gather inside colonies and disperse en masse in response to external environmental triggers such as torrential rains at the onset of the wet season. Because this switch from nonreproductive to reproductive development occurs in the presence of king and queen pheromones (i.e., it is not inhibited by these compounds), and appears instead to be triggered by external seasonal cues, the switch to reproductive development must involve not one, but at least two different environmental triggers, and very likely two different polyphenic mechanisms.

Unfortunately, the hormonal control of termite reproductive development is not well understood. In part this is due to the complexity of the polyphenism (many different "switches" are involved, and several of these have multiple critical periods spread over several subsequent molts), and in part due to the lack of sensitive bioassays for the activity of termite endocrine glands. The best assay to date was developed by Greenberg and Tobe (1985) to monitor *in vitro* CA activity for *Zootermopsis angusticollis*. In this species, the pheromonal secretions of the royal pair inhibited JH biosynthesis rates in larvae, suggesting a possible link between pheromonal cues and polyphenic regulation of larval development – at least for the switch between larvae and replacement kings and queens (Greenberg and Tobe, 1985). Specifically, this suggested that high levels of JH might be required for development into the reproductive form.

The endocrine regulation of seasonal alate production is more difficult to study, because production of alates depends on seasonal factors, and not just the presence or absence of the social pair. However, studies of Lanzrein *et al.* (1985) suggest that termite queens may transfer hormones to their eggs, and in this fashion affect the production of alate reproductives. Specifically, they found that in two *Macrotermes* species, queens transferred both JH and ecdysteroids to their eggs, and elevated levels of these hormones during embryonic development biased larvae towards becoming alate reproductives. Although there was considerable individual and seasonal variation in the hormone levels detected in this study, leading the authors to be very cautious in their conclusions, both these results, and those of Greenberg and Tobe (1985), suggest that high levels of JH may be associated with a switch to reproductive forms.

3.13.2.3.2. Larva to soldier polyphenism Much more effort has been put into studies of the endocrine regulation of soldier development. Soldier castes are the hallmark of termite societies. Soldiers have heavily sclerotized exoskeletons and specialized structures for colony defense, including either enlarged mandibles, or enlarged heads that squirt sticky glandular secretions capable of entangling attacking insects.

In the higher termites, soldiers develop from larvae through two successive molts. Larvae develop first into a presoldier, and then undergo a terminal molt into a soldier. As with reproductive development, termite soldier development is triggered by exposure to pheromones within the colony. For example, in *Nasutitermes lujae*, existing soldiers secrete a frontal gland substance that inhibits larvae from differentiating into new soldiers, whereas the royal pair appears to stimulate soldier development via another pheromone (Lefeuve and Bordereau, 1984; Bordereau and Han, 1986). Exposure to colony pheromones is thought to affect larval development through changes in levels of JH, as it did with reproductive development. Specifically, high levels of JH coinciding with high levels of ecdysteroid promotes differentiation of larvae first into presoldiers, and then into soldiers (review: Hartfelder, 2000). In *Macrotermes michaelseni*, increased JH titers during or after the high ecdysteroid peaks of both the presoldier or the soldier molt appear to enhance cuticle deposition in soldier head capsules and mandibles (Okot-Kotber, 1983). Such increases in JH titers have also been shown to be associated with the presence of JH binding proteins in different species of termites (Okot-Kotber and Prestwich, 1991a, 1991b).

In summary, levels of JH during at least two critical periods underlie polyphenic switching between termite castes. Elevated levels appear to set the stage for development into reproductives, and into soldiers, whereas low JH titers appear to favor development into a terminal worker caste (higher termites) or into a pseudergate (lower termites) that still remains flexible in its developmental potential. A critical and yet unresolved question in this context is how a larva can distinguish between soldier and reproductive development, given that both are triggered by high levels of JH. One possibility is that the critical periods of these polyphenisms are separated in time. High levels of JH that occur early during critical larval instar(s) (i.e., before the molting pulse

of ecdysteroids) could be biasing development into prereproductives and reproductives, whereas levels of JH present during the molting pulse of ecdysteroids may open the path to soldier development. This would suggest a synergistic interaction between JH and ecdysteroids in soldier development, as indicated by the findings of Okot-Kotber (1983).

The problem of caste differentiation in termites has gained new impetus from pioneering studies of differential gene expression in the soldier developmental pathway (Miura *et al*., 1999; Miura, 2001). These studies led to the identification of a gene with soldier-specific expression (*SOL1*) in the mandibular gland of the damp-wood termite *Hodotermopsis japonica*. This gene encodes a novel protein with a putative signal peptide, indicating that it may be a soldier-specific secretory product of this gland. The gland develops from a disc-like structure once a presoldier-differentiating molt has been induced by a high JH titer (Ogino *et al*., 1993; Miura and Matsumoto, 2000). Such studies are now capable of providing direct links from hormone titer modulation through gene expression to morphogenesis.

3.13.3. Polyphenism in the Holometabola

In contrast with the Hemimetabola, wing length polyphenism does not play a prominent role in the Holometabola. In this group, the prevalent forms of polyphenism are related either to camouflage, such as in color and wing pattern polyphenism in butterflies, to reproductive strategies, such as the development of weaponry in male stag and rhinoceros beetles, or to reproductive division of labor as in the female castes of many Hymenoptera.

3.13.3.1. Lepidoptera

3.13.3.1.1. Pupal color polyphenism Lepidopteran pupae display a remarkable crypsis; this immobile life stage is especially vulnerable to predators, and pupae rely on hiding for survival (Baker, 1970; Wiklund, 1975; Hazel, 1977; West and Hazel, 1982, 1985; Sims, 1983; Hazel *et al*., 1998). Most butterflies pupate in the soil or leaf-litter, and pupae are generally constitutively brown (West and Hazel, 1979, 1996). However, a number of species crawl out of the leaf-litter to pupate on the undersides of leaves or branches. Wandering larvae in these species encounter a variety of substrate "backgrounds," and effective pupal crypsis requires a facultative mechanism of pigment production (West and Hazel, 1979, 1982, 1996; Hazel and West, 1996; Hazel *et al*., 1998).

Over a century ago it was observed that some butterfly species switch between light and dark pupal forms (e.g., green versus brown), depending on the background substrate (Wood, 1867; Poulton, 1887; Merrifield and Pouldton, 1899). Today, numerous representatives of four lepidopteran families (Danaidae, Nymphalidae, Papilionidae, and Pieridae) are known to exhibit facultative pupal color polyphenism. Depending on the specific habitats and pupation substrates of each species, larvae couple pupal color production with exposure to a variety of external stimuli, e.g., photoperiod (Ishizaki and Kato, 1956; Sheppard, 1958, West *et al*., 1972), relative humidity (Ishizaki and Kato, 1956; Smith, 1978), background color (Wiklund, 1972; Gardiner, 1974; Smith, 1978), and background texture and substrate shape/size/geometry (Sevastopulo, 1975; Hazel, 1977; Hazel and West, 1979).

Pupal color polyphenism appears to be regulated by a threshold (Hazel, 1977; Sims, 1983). Although a continuous range of pupal phenotypes is possible (e.g., West *et al*., 1972), natural populations tend to be dimorphic for pupal color, and genetic studies indicate heritable differences among populations for the sensitivity of animals to background substrate characteristics (Hazel, 1977; Hazel and West, 1979; Sims, 1983).

Prepupal larvae pass through a "sensitive period" (West and Hazel, 1985) when environmental cues associated with pupation substrate influence the release of a neuroendocrine factor (e.g., Hidaka, 1961a, 1961b; Smith, 1978, 1980; Awiti and Hidaka, 1982; Bückmann and Maisch, 1987; Starnecker and Bückmann, 1997). Interestingly, the effect of this factor differs among the lepidopteran families studied.

In Papilionidae, release of this factor (called browning hormone) results in production of a dark (brown) pupa; inhibition of release of this factor results in a light (green) pupa, e.g., *Papilio xuthus*, *P. polytes*, *P. demoleus*, *P. polyxenes*, *P. glaucus*, *P. troilus*, *Eurytides marcellus*, and *Battus philenor* (Hidaka, 1961a, 1961b; Smith, 1978; Awiti and Hidaka, 1982; Hallffter and Edmonds, 1982; Starnecker and Haze, 1999). In contrast, in Nymphalidae (*Inachis io*), Pieridae (*Pieris brassicae*), and Danaidae (*Danaus chrysippus*), the default pupal color appears to be relatively dark (green), and release of the neuroendocrine factor (called pupal melanization-reducing factor (PMRF)) stimulates production of a light (yellow) pupa (Ohtaki, 1960, 1963; Maisch and Bückmann, 1987; Smith *et al*., 1988; Starnecker, 1997). Thus secretion of the neuroendocrine factor has opposite effects on the relative darkness of pupae.

Starnecker and Hazel (1999) extracted the respective neuroendocrine factor from ventral nerve chains

of both a nymphalid (*I. io*) and a papilionid (*Papilio polyxenes*), and injected these neurohormones into sensitive-stage larvae of both the appropriate and the opposite species. In all cases, animals responded to neuroendocrine injections in the species-appropriate way. For example, nymphalid larvae responded to injection of either PMRF (appropriate) or browning factor (inappropriate) by production of light pupae, while papilionid larvae responded to injection of these same substances by production of dark pupae. Cross-reactivity of these neuroendocrine factors suggests that they are in fact the same factor, and indicates that nymphalid and papilionid butterflies may have independently evolved the capacity to facultatively regulate pupal color (Starnecker and Hazel, 1999). Interestingly, although these butterfly lineages appear to have co-opted the same neuroendocrine factor, they coupled it with downstream processes of pigment synthesis that are very different (Starnecker and Hazel, 1999).

3.13.3.1.2. Seasonal wing pattern polyphenism in butterflies A multitude of butterfly species display seasonal polyphenisms for wing pattern and color. Here two of the more common, and better characterized, of these forms of wing pattern polyphenism (light versus dark hindwings and presence or absence of ventral forewing eyespots) are reviewed.

3.13.3.1.2.1. Light versus dark hindwings The most common form of butterfly wing polyphenism involves the overall lightness or darkness of wings. Numerous species in at least four lepidopteran families are characterized by distinct seasonal light and dark forms, and where it has been studied, this seasonal variation in wing pigmentation results from larval sensitivity to both photoperiod and temperature (Weismann, 1875; Süffert, 1924; Müller, 1955, 1956; Aé, 1957; Watt, 1968, 1969; Reinhardt, 1969; Hoffman, 1973, 1978; Shapiro, 1976; Endo and Funatsu, 1985; Endo and Kamata, 1985; Endo *et al*., 1985, 1988; Kingsolver, 1987; Koch and Bückmann, 1987; Kingsolver and Wiesnarz, 1991; Smith, 1991; Nylin, 1992; Jacobs and Watt, 1994).

Wing darkness is known to affect the solar absorption and thermal characteristics of butterflies (Watt, 1968, 1969; Kingsolver and Watt, 1983; Kingsolver and Wiesnarz, 1991; Jacobs and Watt, 1994), and natural selection for physiological performance under seasonally variable temperature regimes likely underlies many of these wing-darkness polyphenisms (Kingsolver, 1987, 1995a, 1995b; Kingsolver and Wiesnarz, 1991). Animals with dark wings are effective at absorbing solar radiation (Watt, 1968, 1969; Kingsolver and Watt, 1983; Kingsolver, 1987). These animals warm quickly, and perform well under cool conditions (e.g., spring), but these same animals are prone to lethal overheating under warmer (e.g., summer) conditions. Most butterfly species with light–dark polyphenisms produce dark forms when animals are reared under short days and cool temperatures (i.e., animals that will emerge in the spring), and lighter forms when they develop under longer days and warmer conditions.

To date, five species have been examined for endocrine regulation of wing melanism polyphenism: the lycaenid *Lycaena phlaeas* (Endo and Kamata, 1985), the papilionid *Papilio xuthus* (Endo and Funatsu, 1985; Endo *et al*., 1985), and the nymphalids *Polygonia c-aureum* (Fukuda and Endo, 1966; Endo, 1984; Endo *et al*., 1988), *Araschnia levana* (Koch and Bückmann, 1985, 1987), and *Junonia (Precis) coenia* (Rountree and Nijhout, 1995).

Although these species represent three families, and they differ in the direction of the polyphenism (i.e., which morph is induced under each set of conditions), and in whether or not the polyphenism is tied with facultative induction of diapause, the underlying physiological mechanisms show many similarities. All of these polyphenisms respond to both photoperiod and temperature, and although each factor can influence wing pattern expression independently, the effects of these environmental variables are additive in all cases. All of these polyphenisms involve critical periods of hormone sensitivity that occur early in the pupal period, and all but one involve the relative timing of the rise in ecdysteroids: when ecdysteroid levels are low during the critical period (i.e., when the pupal peak in ecdysteroid levels starts after the polyphenism sensitive period), then the default wing morph develops (e.g., *L. phlaeas* (Endo and Kamata, 1985); *A. levana* (Koch and Bückmann, 1987); *P. coenia* (Rountree and Nijhout, 1995); and probably *P. c-aureum*, (Endo *et al*., 1988) (see also Rountree and Nijhout (1995)). When the ecdysteroid pulse is induced to start earlier, then high levels of 20E are present during the critical period, and animals switch to production of the alternate morph (**Figure 6**).

The link between external stimulation (e.g., exposure to temperature) and the timing of ecdysteroid secretion involves the brain, and secretion of neurohormones – either prothoracicotropic hormone (PTTH) (see **Chapter 3.2**) (presumed for *A. levana* (Koch and Bückmann, 1987) and *P. coenia* (Rountree and Nijhout, 1995)), or another neurohormone called summer morph producing hormone (SMPH) (Fukuda and Endo, 1966; Endo and Funatsu, 1985; Endo and Kamata, 1985), that has

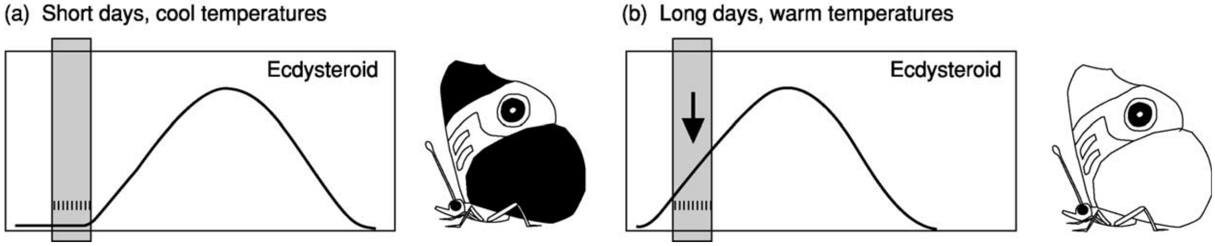

Figure 6 Seasonal wing color polyphenism in butterflies, as exemplified in *Junonia (Precis) coenia,* represents the outcome of an interaction between allelic differences (genetic polymorphism for wing color) and environmental conditions. (a) Larvae exposed to a short-day photoperiod and low temperature regime secrete low levels of a small prothoracicotropic hormone (PTTH)-like neurohormone at the onset of the pupal phase. Consequently, the pupal ecdysteroid peak builds up late and reaches threshold levels only after the critical period (grey bar). This permits the expression of dark pigments in the developing wings which are, thus, adapted for higher solar absorption. (b) In contrast, exposure of larvae to a long-day photoperiod and high temperatures leads to an early and enhanced PTTH release, and consequently above-threshold ecdysteroid levels during the critical period. These conditions favor the expression of the light-colored, alternative wing phenotype. Based on data by Masaki, T., Endo, K., Kumagai, K., **1988**. Neuroendocrine regulation of development of seasonal morphs in the Asian comma butterfly, *Polygonia c-aureum* L.: is the factor producing summer morphs (SMPH) identical to the small prothoracicotropic hormone (4K-PTTH)? *Zool. Sci. 5*, 1051–1057; Rountree, D.B., Nijhout, H.F., **1995**. Genetic control of a seasonal morph in *Precis coenia* (Lepidoptera, Nymphalidae). *J. Insect Physiol. 41*, 1141–1145, and other references cited in the text.

structural similarities to both bombyxin and small PTTH (Masaki *et al*., 1988; Rountree and Nijhout, 1995). Extirpation of brains in animals prevents release of these neurohormones, and results in complete production of the default morph (e.g., Fukuda and Endo, 1966; Endo and Funatsu, 1985; Endo and Kamata, 1985; Endo *et al*., 1988; Rountree and Nijhout, 1995). However, injection of ecdysteroids as these brainless animals pupate (i.e., prior to the critical period) can restore the polyphenism, and switch animals to the alternate form (Endo and Kamata, 1985; Koch and Bückmann, 1987; Rountree and Nijhout, 1995).

These results suggest the following model for light–dark polyphenism in butterflies (summarized for *P. coenia* in **Figure 6**): environmental stimuli affect the timing of ecdysteroid secretion indirectly, via neurohormone secretion by the brain. Larvae exposed to warm temperatures and long days produce high levels of neurohormone. High neurohormone levels stimulate early secretion of ecdysteroids, and early secretion of ecdysteroids switches animals to production of the alternate (generally the lighter) morph.

3.13.3.1.2.2. Presence/absence of eyespots Some butterfly species exhibit seasonal polyphenism for pattern elements, in addition to, or instead of, seasonal variation in overall levels of melanization (Condamin, 1973; Shapiro, 1976; Brakefield and Larsen, 1984; Brakefield and Reitsma, 1991; Roskam and Brakefield, 1999). A striking example occurs in the satyrid *Bicyclus anynana*, which exhibits a wet versus dry season polyphenism for presence (and size) of eyespots (Brakefield and Reitsma, 1991; Windig *et al*., 1994; Kooi *et al*., 1996; Brakefield *et al*., 1998). Wet-season animals express pronounced ventral wing eyespots that are reduced or absent in dry-season animals.

Ventral eyespots are thought to aid animals in surviving attacks by avian predators because they misdirect the aim of the predator (Brakefield and Larsen, 1984; Wourms and Wassermann, 1985; Windig *et al*., 1994). Wet-season animals are active (feeding, mating, and ovipositing), and are regularly exposed to avian predators, and it is presumed that these animals survive better with pronounced eyespots. Dry-season animals are almost completely dormant, and escape predators through crypsis. These animals achieve better crypsis if they do not produce conspicuous markings such as eyespots (Brakefield and Larsen, 1984; Brakefield and Reitsma, 1991; Windig *et al*., 1994).

Eyespot polyphenism in *B. anynana* results from larval sensitivity to temperature (Brakefield and Reitsma, 1991; Kooi *et al*., 1994; Windig *et al*., 1994; Brakefield and Mazotta, 1995; Kooi and Brakefield, 1999). Late-stage larvae exposed to temperatures above 23 °C produce the “wet-season” pattern with large eyespots. Larvae exposed to temperatures below 19 °C produce the “dry-season” form with tiny or no eyespots (Brakefield and Mazotta, 1995; Brakefield *et al*., 1998). Interestingly, although natural populations of these butterflies are dimorphic, this developmental mechanism (like the light–dark polyphenism described in the previous section, incidentally) does not seem to involve a threshold: intermediate temperatures lead to intermediate eyespot sizes, and animals reared in the laboratory can be induced to produce a continuous

range of wing patterns (Windig *et al.*, 1994). Instead, dimorphism appears to arise from distinct seasonal temperature regimes encountered by sequential generations of larvae in the wild (Windig *et al.*, 1994).

Temperature-induced variation in eyespot size appears to be mediated by the timing of the pupal pulse of ecdysteroids (Koch *et al.*, 1996; Brakefield *et al.*, 1998). Just as with the light–dark polyphenism in *A. levana* and *P. coenia*, animals have a hormone-sensitive period during the first few days of the pupal period. The default developmental pathway appears to be a pupal pulse of ecdysteroids that starts after this critical period. When ecdysteroid levels are low during the sensitive period, no eyespots form (the dry-season form). Wet-season (warm-temperature) animals have an earlier pulse of ecdysteroids that precedes the sensitive period, and the presence of ecdysteroids during this period results in the production of large eyespots (Koch *et al.*, 1996; Brakefield *et al.*, 1998).

Genetic strains of *B. anynana* that have been selected for continuous expression of the no-eyespot morph have late pulses of ecdysteroids identical to those of the cool-temperature-induced dry-season animals (Koch *et al.*, 1996; Brakefield *et al.*, 1998). However, these genetically eyespotless animals can be induced to produce eyespots by injections of 20E prior to the sensitive period (Koch *et al.*, 1996). These results all point to a mechanism where polyphenic expression of butterfly eyespots results from a coupling of larval exposure to temperature with variation in the timing of secretion of ecdysone during the first 2 days of the pupal period (**Figure 7**).

Butterfly eyespots have served as a model system for characterizing the developmental control of pattern formation (Kühn and von Engelhardt, 1933; Nijhout, 1985, 1986, 1991; French and Brakefield, 1995; French, 1997; Brunetti *et al.*, 2001; Beldade and Brakefield, 2002; McMillan *et al.*, 2002), and recent genetic experiments provide exciting glimpses into the patterns of gene expression that underlie eyespot formation in general, and temperature-sensitive modulation of eyespot size in particular.

Butterfly eyespots result from a patterning mechanism that takes place in the wings of late-larval and early stage pupae (Nijhout, 1985, 1986, 1991; French and Brakefield, 1995; French, 1997; Brunetti *et al.*, 2001; Beldade and Brakefield, 2002). Briefly, the eyespot consists of a series of concentric pigmented rings around an organizing center, or focus. Cells in the focus of an eyespot are critical for normal formation of the eyespot: if these cells are ablated at the end of the larval period, eyespots fail to form (Nijhout, 1980, 1991; Nijhout and Grunert, 1988). Likewise, if foci cells are transplanted, they can induce ectopic eyespots in other parts of the developing wing (Nijhout, 1991; French and Brakefield, 1995; Brakefield *et al.*, 1996). It appears that foci establish the eyespot by secreting a diffusable chemical morphogen into the surrounding epidermis, and that this signal is interpreted by the surrounding cells in a way that affects the color of the pigment synthesized; gradient contours in the diffusable substance interact with the relative sensitivities of the surrounding cells to generate the concentric rings of the eyespot.

Although the identity of the morphogen released from eyespot foci is not yet known, recent genetic studies using antibodies for *Drosophila* patterning genes have identified several signaling molecules and transcription factors expressed in the appropriate areas, and at the appropriate times (Carlin *et al.*, 1994; Brakefield *et al.*, 1996; Keys *et al.*, 1999; Weatherbee *et al.*, 1999; Brunetti *et al.*, 2001; Beldade and Brakefield, 2002). For example, *distal-less*, *engrailed*, and *spalt* all have circular regions of expression that correspond with the position of eyespots (Brakefield *et al.*, 1996; Keys *et al.*, 1999; Brunetti *et al.*, 2001; Beldade *et al.*, 2002) and their expression occurs at the time of eyespot pattern formation (late-larval and early pupal period). All three genes are expressed together in the organizing focus of the eyespot, but they are expressed separately in the surrounding color rings, lending credence to the idea that they may in some way contribute to the patterning of the rings themselves (Brunetti *et al.*, 2001; Beldade and Brakefield, 2002).

Brakefield and colleagues have taken the next step by linking expression patterns of these genes – *distal-less* in particular – with quantitative variation in eyespot size. Genetic lines selected for large and small eyespots differ in the relative size of the eyespot focus, as measured by the region of *distal-less* expression (Monteiro *et al.*, 1994, 1997; Beldade and Brakefield, 2002; Beldade *et al.*, 2002). Beldade *et al.* (2002) then showed that genetic variants of *distal-less* expression cosegregate with interindividual variation in eyespot size.

Combined, these studies suggest an explicit model for the developmental basis of variation in eyespot size (after Beldade and Brakefield (2002)): differences in the relative amount of growth of the organizing focus lead to differences in the size of the focus at the time of pattern formation. This translates into the strength of the signal emitted from this organizing center, and results in relatively larger or smaller eyespot diameters. Plasticity in the expression of eyespot size could then result from a coupling of the amount of growth of the organizing

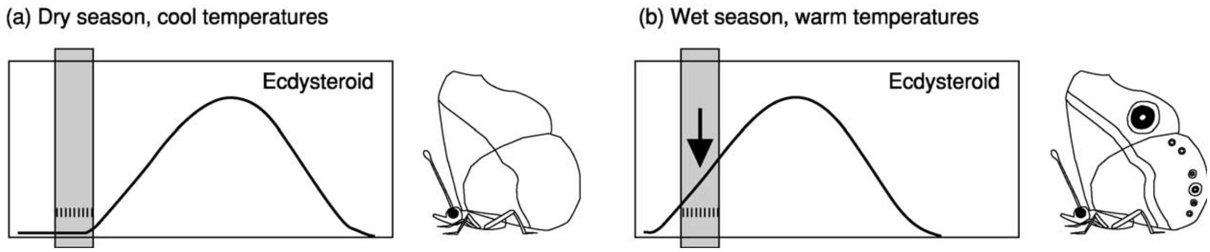

Figure 7 Eyespot size polyphenism as exemplified in the tropical butterfly *Bicyclus anynana*. (a) The less active dry-season (low temperature) morph has no or tiny eyespots on the ventral side of the forewings, as a result of a low ecdysteroid titer during the critical period (shaded bar) at the onset of pupal development. (b) In contrast, the wings of the wet-season (high temperature) morph develop large eyespots in response to an above-threshold ecdysteroid titer during this critical period. In the wing discs of last instar larvae, eyespot focal cells express the Distal-less protein. The earlier pupal ecdysteroid peak causes enhanced synthesis of dark pigment from these focal centers and consequently generates large eyespots in the wet-season morph. Based on data and models by Brakefield, P.M., Reitsma, N., **1991**. Phenotypic plasticity, seasonal climate and the population biology of *Bicyclus* butterflies (Satyridae) in Malawi. *Ecol. focus with the amount of ecdysteroid present during the patterning period (Koch *et al.*, 2003). Wet-season (higher temperature) animals would have early rises in pupal ecdysteroid levels, stimulating growth of large eyespot foci, and resulting in correspondingly large adult eyespots; whereas dry-season (lower temperature) animals would have later rises in pupal ecdysteroid levels, less hormone present during the sensitive period, less growth of the eyespot foci, and relatively smaller final eyespots (**Figure 7**).

Interestingly, not all eyespots are plastic – even within the same individual. In *B. anynana* ventral forewing eyespots are exquisitely sensitive to the larval thermal environment, but dorsal eyespots are not. Dorsal eyespots are expressed in all individuals, and display no detectable plasticity. Brakefield *et al.* (1998) propose that this difference in the environmental sensitivity of expression of dorsal and ventral eyespots results from the presence of ecdysteroid receptors (see **Chapter 3.5**) in the foci of ventral eyespots, and the absence of these same receptors in the focal cells of the dorsal eyespots. Thus patterns of ecdysone receptor expression may underlie the coupling of an adult wing pattern element expression (eyespots) with seasonally variable components of the larval environment (temperature).

3.13.3.2. Coleoptera: Male Dimorphism for Weaponry

Males of many species face intense competition from rival males over access to reproduction (Darwin, 1871; Thornhill and Alcock, 1983; Andersson, 1994). In these species, it is not uncommon for dominant and subordinate individuals to adopt different behavioral tactics: dominant (generally large) males fight to guard territories frequented by females, or display or sing to attract females, while subordinate (generally smaller) males of these same species adopt less aggressive alternative tactics, such as sneaking up to, or mimicking, females (Darwin, 1871; Austad, 1984; Dominey, 1984; Gross, 1996; Iguchi, 1998; Shuster, 2002).

In the most extreme cases, large and small males differ in morphology as well as reproductive behavior. Rarely, these alternative male “morphs” result from allelic differences among the male types (e.g., Shuster, 1989; Zimmerer and Kallmann, 1989; Ryan *et al.*, 1990; Lank *et al.*, 1995). However, the majority of male dimorphisms appear to result from polyphenic developmental processes that switch among alternative phenotypic possibilities depending on larval growth, and/or the resulting body size attained by each individual (e.g., Kukuk, 1996; Eberhard, 1982; Goldsmith, 1985, 1987; Rasmussen, 1994; Clark, 1997; Tomkins, 1999). Males encountering

favorable conditions grow large, and produce one morphology, while genetically similar (e.g., sibling) individuals encountering poor conditions remain small, and produce an alternative morphology. These male-dimorphic polyphenisms are characterized by a relatively abrupt switch between morphs that corresponds with a critical, or threshold, body size (e.g., Diakonov, 1925; Kukuk, 1966; Cook, 1987; Danforth, 1991; Eberhard and Gutierrez, 1991; Rasmussen, 1994; Kawano, 1995; Tomkins and Simmons, 1996; Iguchi, 1998).

To date, only one male dimorphism that we are aware of has been characterized physiologically: the alternative horn morphologies of the dung beetle *Onthophagus taurus* (Coleoptera: Scarabaeidae). This is a European species that has been introduced into both Australia and the USA, where it is now an abundant inhabitant of horse and cow manure (Fincher and Woodruff, 1975; Tyndale-Biscoe, 1996).

Beetles fly into fresh manure pads and excavate tunnels into the soil below. Females dig the primary tunnels, and spend a period of days pulling fragments of dung to the ends of these tunnels, where they pack them into oval masses called "brood balls" (e.g., Fabre, 1899; Hallffter and Edmonds, 1982; Emlen, 1997; Moczek and Emlen, 2000). A single egg is laid inside each brood ball, and larvae complete their development in isolation within these buried balls of dung (Fabre, 1899; Main, 1922; Emlen and Nijhout, 1999, 2001).

Male behavior revolves around methods of gaining entry to tunnels containing females. Large males fight to guard tunnel entrances, while smaller males sneak into these tunnels on the sly (Emlen, 1997; Moczek and Emlen, 2000). Large males produce a pair of long, curved horns that aid them in contests over tunnel occupancy (Moczek and Emlen, 1999). Smaller males dispense with horn production altogether.

Both overall body size and male horn length are sensitive to the larval nutritional environment (Emlen, 1994; Hunt and Simmons, 1997; Moczek and Emlen, 1999). Specifically, the amount and quality of larval food predictably influence the final body size and horn lengths of males (Emlen, 1994; Hunt and Simmons, 1997; Moczek and Emlen, 1999). Controlled breeding experiments, artificial selection experiments, population comparisons, and "common garden" experiments all suggest that horn expression is regulated by a threshold mechanism, and that natural populations contain measurable levels of additive genetic variation for the body size threshold, i.e., the size associated with the switch between horned and hornless morphologies (Emlen, 1996; Moczek *et al*., 2002). Somehow, then, the relative amount of growth of the horns must be influenced by the overall growth – or body size – attained by each animal. Specifically, this polyphenism appears to involve a reprogramming of animals that fall beneath a genetically mediated threshold body size, so that in these animals, growth of the horns is reduced.

Beetles pass through three larval instars before molting into a pupa (Main, 1922; Emlen and Nijhout, 1999). Larvae feed on dung supplies that are provided in the brood ball, and gain weight steadily. When these food supplies are depleted, a stereotyped series of events is commenced which ultimately results in the metamorphic molt from larva to pupa (Emlen and Nijhout, 1999). The cessation of feeding appears to trigger a rapid drop in JH titers analogous to the drop that occurs with attainment of a critical size for metamorphosis in *Manduca sexta* (Nijhout, 1994). Animals stop feeding, they begin to purge their gut, they begin forming a mud/fecal shell that will protect them as pupae, and the imaginal structures (legs, wings, genitalia, horns) begin growth.

A combination of hormone-application perturbation experiments (JH) and radioimmune assays of hormone titer profiles (ecdysteroids) revealed two critical periods relevant to this developmental polyphenism. Perturbation of hormone levels during either of these sensitive periods influences the expression of male horns, though the effects of hormone application at these two times are distinct (Emlen and Nijhout, 1999, 2001). The first of these critical periods occurs at the end of the feeding period, before initiation of the metamorphic molt. Animals at this time have attained their largest sizes, and larval weight during this period exactly predicts patterns of male horn expression: male larvae with sustained weights equal to or heavier than 0.12 g end up producing horns, whereas male larvae not sustaining this critical weight end up not producing horns (Emlen and Nijhout, 2001). Furthermore, male larvae with weights beneath this critical size have a small pulse of ecdysteroids that is not present in larger males (**Figure 8**). These results suggest that body size is assessed at this time, and that animals beneath a critical larval weight are "reprogrammed" by a morph-specific pulse of ecdysteroids. Levels of JH appear to be involved in this size-assessment process. Topical application of the JH analog methoprene during this critical period raised the threshold body size associated with horn expression, so that methoprene-treated animals needed to attain a larger body size (heavier larval weight) for horn production than acetone-treated control animals (Emlen and Nijhout, 2001).

A second critical period occurs after the metamorphic molt has been initiated, as animals purge their guts and enter the prepupa period. This is the period of horn growth. All of the imaginal structures, including the horns, are growing rapidly at this time, and all animals have very high levels of ecdysteroids irrespective of sex or morph (Emlen and Nijhout, 2001). Here again, levels of JH appear correlated with body size, and perturbation of levels of JH influences the relative amount of growth of imaginal structures. In this case, augmentation of levels of JH (by topical application of methoprene) caused animals to produce disproportionately large horns. Specifically, it caused small, typically hornless males, to produce horns (Emlen and Nijhout, 1999).

In summary, experiments to date suggest that there are two periods during larval development when horn expression is sensitive to endocrine events. A first critical period occurs as animals attain their largest body sizes, and animals not attaining (or sustaining) a threshold size get reprogrammed by a small, morph-specific pulse of ecdysteroids at this time (**Figure 8**). Ecdysteroids affect patterns of gene transcription and are known to reprogram the developmental fates of specific structures (e.g., epidermis, imaginal discs) (review: Nijhout, 1994) (see **Chapter 3.5**)). In this case, a pulse of ecdysteroids appears to reprogram the relative sensitivity of cells destined to become the horns, so that their growth is inhibited during the second critical period, the period when all of the imaginal structures grow to their final sizes (not shown).

3.13.3.3. Hymenoptera: Caste Polyphenism and Division of Labor

Except for termite caste polyphenism, most of the examples discussed so far can easily be accomodated within the framework of classic Darwinian fitness concepts, wherein alternative phenotypes prove to be intimately related to alternative reproductive strategies. In principle, each of the selective environments encountered by insects (e.g., spring versus summer) favors a different optimal phenotype, and individuals maximize their reproductive success by expressing the appropriate morphology in the appropriate circumstance.

Caste polyphenisms, in contrast, are associated with a severe reduction in fertility of the subdominant (worker) caste. In fact, workers in most social insect colonies never reproduce. Social insect societies with their complex caste systems thus do not obey the rules of classical Darwinian theory, a fact that has clearly and succinctly been stated by Darwin (1859). The dilemma of inserting social insect castes into a fully acceptable Darwinian framework was only resolved by the introduction of the theory of "inclusive fitness" (Hamilton, 1964). Since then, a great deal of work has centered on the evolutionary significance of sterile worker individuals within social insect colonies, and in

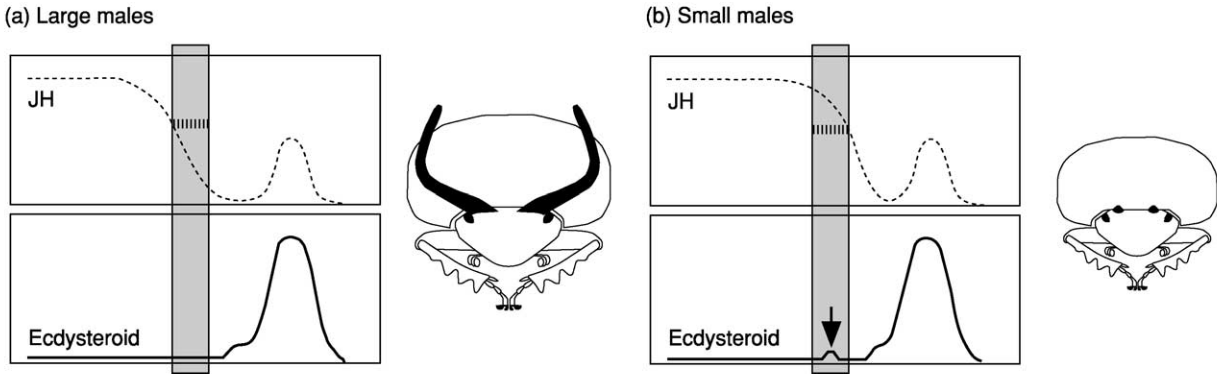

Figure 8 Hormonal control of horn length in males of the dung beetle *Onthophagus taurus*. Horn length is associated with a male's capacity to defend the entry tunnel to a burrow of an egg-laying female. It follows a nonisometric (sigmoid) relationship with respect to variation in male size. Growth of the horn morphogenetic field is determined during two hormone-sensitive periods in the last larval instar. The first one (shaded bars) occurs at the end of the feeding period when the larvae have reached their maximal weight. (a) In male larvae that passed the critical weight limit, the JH titer drops below a critical threshold during this first critical period. (b) In contrast, smaller larvae conserve an elevated JH titer and exhibit a small ecdysteroid peak which is supposed to reprogram the horn morphogenetic field so as not to permit horn growth during metamorphosis. The second critical period occurs during the prepupal phase (not shown) when the elevated JH titer promotes horn growth in the large males only. Graph based on studies by Emlen, D.J., **1994**. terms of ultimate explanations, the principal framework of caste evolution in social insects has now become firmly established.

What remain to be elucidated are (1) the proximate mechanisms that drive an individual insect to become a sterile worker or a full reproductive, and especially (2) the evolution of these proximate mechanisms, i.e., the evolution of developmental pathways that generate the distinct queen/worker and also the soldier phenotypes. Even though consistent in argumentation, most attempts to describe evolutionary tendencies in caste development are notorious for their lack of connection to physiological mechanisms, especially hormonal regulation, underlying the divergent differentiation pathways for the caste phenotypes. Only if it becomes possible to map these physiological mechanisms onto a phylogenetic framework may a unifying picture of caste evolution emerge which satisfies both proximate and ultimate explanations.

The diversity in caste syndromes and the manifold stimuli that trigger caste differentiation remain a challenge to any unifying view of developmental regulation. In part, the root of this problem lies in the conceptual framework of caste, that is, which aspects of caste are emphasized by different authors. In the most general sense, the term "caste" is used to describe functional roles in reproduction and division of labor, such as the performance of different tasks by different members of an insect society. In a more restricted sense, caste is seen as a manifestation of preimaginal developmental diversification resulting in distinct phenotypes which are then ever more prone to perform distinct functions in division of labor. Distinct caste phenotypes are a hallmark of the highly eusocial insect societies, and in a discussion of insect polyphenism, one might tend to concentrate on this latter aspect. Yet, in terms of evolutionary explanations, that is, how such distinct phenotypes may have emerged from modifications in developmental physiologies and gene expression, it is informative to start with incipient social systems that arise from individual differences in reproductive potential. Subsequently, we will try to discern these two aspects of caste and the underlying endocrine mechanisms that govern behavioral and morphological diversification.

A first and major distinction in social insect organization and caste systems sets apart the hemimetabolous termites from the holometabolous Hymenoptera (wasps, bees, and ants). As already outlined above, termites are diplo-diploid hemimetabolans that descended from presocial cockroaches, and caste development in termites is essentially a problem of how endocrine regulation of postembryonic development can be "manipulated" to maintain immatures as a worker caste, while permitting terminal differentiation of a soldier and a reproductive caste. Sociality in the Hymenoptera, in contrast, arose from asymmetries of genetic relationship generated by the haplo-diploid system of sex determination (Hamilton, 1964), and arose several times independently. Multiple evolutionary origins of sociality makes Hymenoptera, and in particular wasps and bees, useful objects to study the environmental, genetic, and endocrine background that sets the stage for the development of the exclusively female caste phenotypes, the primary ones being queens and workers. Ants, in contrast, are all highly social, and thus are less ideally suited for comparative studies with such a focus. They are most valuable, however, when it comes to testing hypotheses on the evolution of multiple sterile female caste phenotypes, in particular, worker versus soldier development. It is important to emphasize at this point that the soldier caste in ants is a highly derived phenotype which makes its appearance only in a few genera, in contrast to the soldier caste in termites, which is one of the essential features of termite sociality.

In general terms, holometabolous caste phenotypes can be seen as a progressive fixation of roles, first in reproduction, and second in the specialization to specific tasks related to colony maintenance (Wilson, 1971). Evolutionarily, the monopolization of colony reproduction by a queen caste starts out either with asymmetries in the reproductive potential of females that are cofounders of a nest, or from the repression of the reproductive potential of offsping daughters by the mother who persists in the nest. Obviously, in the first case, reproductive dominance should become established through a series of dominance interactions between adult and potentially reproductive females, whereas in the latter case, which requires an overlap of generations, the dominant egg-laying mother may repress reproductive activity in her daughters by manipulating a preimaginal caste bias.

3.13.3.3.1. Wasps As illustratingly stated by West-Eberhard (1996), "wasps are a microcosm for the study of development and evolution" of insect sociality, and they serve as a logical baseline for endocrine studies of caste polyphenism. All social Hymenoptera evolved from wasps (Wilson, 1971), and most levels of sociality can be found within extant wasp taxa. Three of the subfamilies in the Vespidae, the Stenogastrinae, Polistinae, and Vespinae, contain social species (Carpenter, 1991), with the Polistinae being of special interest since they

represent practically the entire range of social evolution. Many of the Old World Polistinae are open-nesting wasps, where colonies can be founded by one or more mated females. In such incipient colonies, a dominance hierarchy is gradually established by aggressive interactions between the females (Sledge *et al.*, 2001). Thereafter, the dominant female signals her status to the subordinate females (Sledge *et al.*, 2001) and whenever she encounters an egg laid by another female she removes it. In such a system, foregoing reproduction with the perspective to eventually substitute the dominant female and take over the nest, has a relatively high value in the payoff matrix, since survival chances of individual nest-founding females generally are quite low.

The endocrine basis of this reproductive dominance has, so far, only been investigated in *Polistes dominulus* (formerly *gallicus*). These studies revealed a synergistic interaction between JH synthesis, ecdysteroid titer, and ovarian activity. Dominant females have a higher CA activity, and consequently a higher JH titer, than subordinate females. In addition, the higher ovarian activity in dominant females also correlates with an elevated ecdysteroid titer. JH and/or ecdysteroid treatment of subordinate females resulted in a rise in their social rank (Barth *et al.*, 1975; Röseler *et al.*, 1984, 1985; Strambi, 1990). Such an interaction in hormonal control of physiology and behavior is a general trait in insect reproduction (see **Chapter 3.9**) and should be expected also in solitary or incipiently social Hymenoptera. These studies, however, also pointed out an important gap in our comprehension of reproductive dominance, that is the distinction between the presence of an activated ovary and high social rank (Sledge *et al.*, 2001). Even when ovariectomized, some *Polistes* foundress females continued to maintain their dominance status (Röseler *et al.*, 1985). Generally these were females with large CA. A large CA volume (and thus presumed high CA activity), however, was not linked consistently to dominance, since in other cases formerly subordinate females that became dominant over ovariectomized foundresses did not have larger CA.

With increasing social complexity the choice between alternative reproductive strategies evidently becomes restricted and, in parallel, morphological caste differences become implemented and increase in degree. This is nicely illustrated in the Ropalidiini where a gradual shift towards a preimaginal caste bias has been demonstrated convincingly (Gadagkar *et al.*, 1988), together with an age-dependent pattern of task performance (temporal or age polyethism) in adult workers (Naug and Gadagkar, 1998). In the Neotropical, swarm-founding Epiponini, morphological caste phenotypes are clearly expressed, ranging from subtle differences between the extremes in a unimodal body size range, to clearly dimorphic castes, resulting from nonisometric growth in the preimaginal phase. In the latter, queens are not necessarily always the largest individuals. Careful allometric analyses suggest size-independent allometries in many of these cases, evidencing preimaginal caste determination marked by a resetting of growth parameters in critical phases of development (Jeanne *et al.*, 1995; Noll *et al.*, 1997; O'Donnell, 1998; Keeping, 2002). Such preimaginal bias of the worker caste towards subfertility and decreased mating tendency has been attributed to nutritional castration by the brood-rearing females (Hunt, 1991). Neither the Ropalidiini nor the Epiponini have been investigated with regard to endocrine system functions in caste development, and only in two species has hormonal control in division of labor among the adult wasps been addressed. The results are of interest as they indicate a split in reaction patterns. In the primitively social *Ropalidia marginata*, an elevated JH titer stimulated egg development (Agrahari and Gadagkar, 2003), whereas in the socially more advanced *Polybia occidentalis*, methoprene accelerated behavioral development in workers (O'Donnell and Jeanne, 1993), similar to what is observed in honeybees (Robinson and Vargo, 1997).

3.13.3.3.2. Ants Ants (and termites) are an apex in caste complexity, and thus also a challenge to any unifying hypothesis on caste development and function. In this review, only a glimpse into the ant empire of behavioral and developmental diversity is provided. Luckily, we can direct any reader interested in a more detailed presentation on ant biology to a masterpiece in scientific literature written by Hölldobler and Wilson (1990). Prior to any further discussion it is important to emphasize that there are no solitary or primitively social ants. Possibly related to a major switch in foraging biology from flying to walking in search of prey, a Mesozoic sphecoid wasplike ancestor ant appears to have been exposed to relaxed selective constraints on the aerodynamics of body shape, making possible a wide variation in worker ant morphologies. This resulted in an eminent wing polyphenism between queens and workers which is present already in the earliest ant fossils (Wilson, 1987). Many early studies on ant sociobiology capitalized on such variation in form, analyzing size allometries in relation to functions performed by colony members and in relation to phylogenetic patterns (reviews: Wilson, 1971; Hölldobler and Wilson, 1990; Wheeler,

1991). Yet, even though there is a wealth of data on complex trait allometries in ants, there still appears to be a lack of information linking these data to rules of how changes in shape are actually generated in development, and how these specific developmental pathways have evolved in the colony context (Tschinkel, 1991; Tschinkel *et al*., 2003).

3.13.3.3.2.1. The queen/worker decision As in all highly social insects, ant queens differ markedly from workers. They are generally bigger, have a fully developed reproductive system, and have a well-developed flight apparatus for dispersal. Even though this queen/worker distinction is an ancestral character present in all ant species, we still have very limited knowledge as to how these caste differences arise ontogenetically. Many of the early studies on mechanisms governing queen production in ants were carried out on temperate climate species, and these indicated strong seasonal triggers of queen production (review: Wheeler, 1986). In many species, queens only are produced from overwintered eggs or larvae, illustrating a requirement for a state of diapause in the development of queens (see **Chapter 3.12**).

For some ants, the critical period for the queen/worker decison has been studied by JH application experiments. For example, topical application of JH to larvae developing from queen-biased overwintered brood in *Myrmica rubra* increased the number of queens (Brian, 1974). In *Aphaenogaster senilis*, application of JH caused the appearance of queen-like workers (Ledoux, 1976), and this same pattern occurred in the Argentinian fire ant, *Solenopsis invicta* (Vinson and Robeau, 1974). In the latter species, metamorphosis was delayed significantly by the application of JH, and the “queenlike” appearance of workers was initially attributed to a simple increase in worker size (associated with the delay in metamorphosis, and extended period of larval feeding), rather than to a direct effect of JH on queen production (Wheeler, 1990).

Ecdysteroids also have been implicated in divergent queen/worker development. In *Plagiolepis pygmea*, worker-biased larvae have higher ecdysteroid titers during the last larval instar than queen-biased larvae (Suzzoni *et al*., 1983).

In all examples cited so far, caste development is overwhelmingly dependent on environmental factors. Yet there is increasing evidence for a genetic basis to the determination of queen/worker polyphenism in at least some species of ants. Such genetic factors (allelic differences between queens and workers) were originally proposed for the slave-making ant *Harpagoxenus sublaevis* (Winter and Buschinger, 1986), but have recently also been demonstrated for a *Camponotus* (Fraser *et al*., 2000) and two *Pogonomyrmex* species (Julian *et al*., 2002; Volny and Gordon, 2002). How these alleles interact with the endocrine system to direct caste development remains to be explored.

Environmental triggers of ant caste development primarily involve pheromonal signals within the colony itself. Pheromonal regulation of ant reproduction has been studied primarily in *S. invicta*, which has completely sterile workers due to the lack of functional ovaries (Hölldobler and Wilson, 1990). Virgin *Solenopsis* queens normally leave on a mating flight, and thereafter shed their wings, activate their ovaries, and soon initate egg-laying. If prevented from flying, these queens keep their wings and maintain their ovaries in an inactive state, and animals are prevented from maturing their ovaries as long as an egg-laying queen is present in the nest (Fletcher and Blum, 1981). This integrated behavioral and physiological response in *Solenopsis* virgin queens has led to the identification of a pheromone produced by the poison gland of the dominant queen which inhibits precocious dealation and ovary activation in virgin queens as long as they are in the nest (Fletcher and Blum, 1983). The pheromone supposedly maintains high brain dopamine levels (Boulay *et al*., 2001) which are thought to suppress CA activity (Vargo and Laurel, 1994; Burns *et al*., 2002). Low CA activity in turn prevents vitellogenin uptake by the ovary. Vitellogenin synthesis appears to occur independently of JH (Vargo and Laurel, 1994), and the decision to initiate oogenesis or not seems to be taken by the activation of receptor-mediated vitellogenin uptake. In *Camponotus festinatus*, such a regulation has also been shown to prevent ovary activation in queenless workers (Martinez and Wheeler, 1991).

The species considered so far all belong to a large group of ants which do not exhibit a marked polyphenism within the worker caste. Instead, they all have a worker caste with unimodal or only slightly bimodal size frequency distributions. In these species, the principal polyphenism is between queens (reproductives) and workers (nonreproductives). In contrast, the genus *Pheidole* is characterized by multiple polyphenisms: between queen and worker, and also between different types of workers (including true soliders). In fact, the genus *Pheidole* exhibits the most spectacular polyphenism known for social insect worker castes (see below). In these taxa, the queen/worker switch occurs much earlier in development than the worker/soldier switch. Queen development in *Pheidole* is determined very early in development, while animals are still embryos,

and appears to be determined largely by hormone levels deposited by the egg-laying mothers.

Despite this change in timing, however, the roles for the two basic hormones appear the same. Queens that laid worker-biased eggs had higher ecdysteroid levels than those laying queen-biased eggs, and, correspondingly, worker-biased eggs also exhibited a higher ecdysteroid content (Suzzoni *et al.*, 1980). Furthermore, JH application to eggs increased the proportion of females developing into queens (Passera and Suzzoni, 1979). These results suggest that even during this early critical period, high levels of ecdysteroids are associated with worker development, and high levels of JH stimulate queen development.

3.13.3.3.2.2. The worker/soldier decision In contrast to the other highly eusocial Hymenoptera, division of labor within ant worker castes does not seem to be governed by age-related shifts in task performance. Rather, it is the relatively large size range of workers that underlies task preference and morphological specialization. Developmental mechanisms underlying worker caste polyphenism have been extensively reviewed (Wheeler, 1991) and mathematical models have been proposed that explicitely address the problem of growth rule reprogramming (Nijhout and Wheeler, 1994). Worker/soldier reprogramming is thought to take place during late larval instars, in response to different feeding conditions or other forms of social influence on larval growth. These, in turn, appear to impact the larval endocrine system, as a regulator of growth and the onset of metamorphosis. Studies exploring this aspect were carried out on *S. invicta*, which has a unimodal distribution of worker size (Wheeler, 1990), and on the strongly polyphenic *Pheidole bicarinata* (Wheeler, 1983, 1984).

Methoprene application to late larval instars led to an increase in size in *S. invicta* workers due to a retarded onset of metamorphosis. In *P. bicarinata*, such treatment resulted in the expression of soldier characters in the emerging brood, indicating a discrete JH-dependent developmental switch in the last larval instar. In species with a bimodal or multimodal size distribution, larvae that reach a critical size and consequently experience a different endocrine milieu can thus be shunted into alternative developmental pathways leading to overt polyphenism, generally between a soldier and a worker caste (Wheeler, 1994). Obviously, by introducing the worker/soldier decision into the late larval stages, the primary decision (queen versus worker) had to be shifted to earlier stages, as clearly occurred in the genus *Pheidole*.

While the role of JH seems to be pretty well established in *Pheidole* soldier/worker polyphenism, the primary triggering factors are still largely hypothetical. Two aspects could be relevant in this context: first, the larva/worker ratio which determines the amount of nursing activity devoted to each larva and, thus, affects body size (Porter and Tschinkel, 1985), and second, social pheromones which inhibit the development of further soldiers once a soldier level appropriate to colony size has been reached (Wheeler, 1991). In terms of colony fitness, such regulatory mechanisms represent the generalized developmental basis for the concept of adaptive colony demographies postulated by Oster and Wilson (1978).

Although our knowledge of the regulatory cascade from feeding and/or pheromonal factors to endocrine activity and consequent programming of growth parameters is still fragmentary, a landmark study on gene networks underlying wing development in ants (Abouheif and Wray, 2002) has provided remarkable insight into downstream consequences of developmental reprogramming. In the wing buds of three ant species exhibiting different degrees of polyphenism, these authors investigated expression patterns of six regulatory genes (*Ultrabithorax, extradenticle, engrailed, wingless, scalloped*, and *spalt*), all of which are functionally conserved in wing development of holometabolous insects. Cessation of wing bud development in worker-determined larvae is a characteristic element in all ants, and in species of the genus *Pheidole* this cessation can occur in two steps. *Pheidole morrisi* soldier larva develop large vestigial forewing discs but no visible hindwing discs, while worker-destined larvae develop neither of these wing discs. Of these six genes, all except for the most downstream one (*spalt*) showed correlated expression patterns for the large forewing disc in soldier-biased larvae. None of these genes, however, was expressed in the forewing disc of worker larvae, or in the hindwing discs of both soldier and worker larvae. Tracing the gene expression patterns through earlier development suggested (1) a gradual shutdown of the gene regulatory network between mid-embryogenesis and the last larval instar and (2) that this patterning network was not interrupted at a single step, as might be expected under the concept of a classical switch mechanism. Instead, this study suggested that many different points in the gene expression cascade were involved. Extending the study to other ant species with lesser degrees of polyphenism (*Neoformica nitidiventris* and *Crematogaster lineolata*) corroborated the findings from *P. morrisi*. This led Abouheif and Wray (2002) to the conclusion that

natural selection may be playing an active role in determining the most efficient route to halting wing development, and may operate directly on different genes in different species. It is a view that opens up exciting perspectives for hormonal effects on the expression of individual genes in the regulatory networks and should stimulate the search for putative hormone response elements in the upstream control region of these genes in a multispecies comparison.

3.13.3.3.2.3. Queen polyphenism, queen loss, and queenless ants, and wing dimorphism in males Notwithstanding its fascination, phenotypic diversity in the worker caste, which includes both continuous size variation and polyphenism, is restricted to only 15% of the ant genera and is mainly found in the highly derived groups. Yet ants in the subfamilies Myrmeciinae and Ponerinae, which are characterized by a number of ancestral traits and are commonly believed to be socially less complex than the “higher” ants, are by no means boring creatures. These subfamilies are of interest because they exhibit graded transitional series between queens and workers (Heinze, 1998), and workers in these ants are often not sterile: they are equipped with large ovaries and spermathecae (Crossland *et al.*, 1988; Ohkawara *et al.*, 1993; Dietemann *et al.*, 2002). In some species workers attain a queenlike morphology but contribute relatively little to colony reproduction, while in others workers contribute substantially (e.g., the colony-founding queen may be substituted by mated intercastes (Heinze and Buschinger, 1987; Peeters and Hölldobler, 1995)). In the most extreme taxa, the queen caste has been completely lost, and all reproduction is carried out by workers which are denominated gamergates (Peeters, 1991).

Since in such queenless ants all females can potentially mate and lay eggs, a reproductive conflict of interest among colony females (as is typical in primitively social insects) is a secondarily evolved consequence. These species resolve this conflict by employing a mixed strategy of aggression by a dominant female and chemical signaling (Peeters *et al.*, 1999; Liebig *et al.*, 2000; Cuvillier-Hot *et al.*, 2001; Monnin and Ratnieks, 2001).

Juvenile hormone plays an interesting role in social dominance and fertility in these queenless ants. In contrast with primitively social wasps, where the JH titer correlates positively with dominance, and especially fertility (see Section 3.13.3.3.1), application of the JH analog pyriproxyfen to queenless ants resulted in a decrease in fertility in the alpha female, and in a loss in dominance rank (Sommer *et al.*, 1993). This decline in social rank was accompanied by corresponding changes in the cuticular hydrocarbon profile (Cuvillier-Hot *et al.*, 2003). Consequently, the idea that queenless ants represent a reversion to a primitive social system appears to be a superficial oversimplification, and does not withstand a critical analysis once underlying developmental mechanisms and hormonal regulation of reproduction are taken into account. An interesting aspect in this context are the wing-disc-derived gemmae, which deserve to be studied in the context of gene regulatory networks underlying wing development in ants.

Shutdown in wing development may not be exclusive to the female sex in ants, but has recently also been shown to occur in males of *Cardiocondyla obscurior*, where a winged and a wingless male morph were found (Cremer *et al.*, 2002). Just as in workers, the loss of wings is not an isolated character state, but is part of a correlated modification in other characters, including reduced eye size. These “workerlike” males have a much prolonged spermatogenesis compared to winged conspecifics and mate exclusively in the nest. This finding is a complete novelty and should stimulate comparative analyses on physiological and genomic events underlying concurrent polyphenism in the two sexes.

3.13.3.3.3. Caste in social bees Social systems with incipient caste differences between dominant egg-laying and subordinate females have originated, multiply and apparently independently, within the Apidea (Michener, 2000). This happened most notably in the Halictinae, the Xylocopinae, and of course, the Apinae, which contain the closely related social tribes Euglossini, Bombini, Apini, and Meliponini.

The halictine bees are an enormous and abundant worldwide group of bees, yet only a few species exhibit some degree of social interaction between females, and even fewer have been studied with respect to their social biology (review: Michener, 1990b). Even in the socially most advanced halictines, caste differences between females in a nest are minimal and are mainly related to body size. Furthermore, with the loss of the dominant female, a new social rank order is established and formerly subordinate females can become dominant, mate, and lay eggs. Since caste is mainly related to adult size, it is not surprising that the size of the pollen ball deposited in the individual brood chambers is a good indicator of sex and caste (Plateaux-Quénu, 1983). Yet slight differences in size do not predict dominance, suggesting that a female’s capacity

to become a foundress is probably determined multifactorially (Yanega, 1989).

In the xylocopine bees, two tribes (Ceratini and Allodapini) present incipient social organization (review: Michener, 1990a). *Ceratina* nests are very small, containing rarely more than two females. These females may be of different size, and both are capable of laying eggs. Yet it is not necessarily the larger bee that produces the majority of offspring (Sakagami and Maeta, 1985).

In the allodapine bees, colony size may be considerably larger, with at least one Australian species reaching a colony size range approximating that of highly eusocial species (Schwarz *et al*., 2002). In the best-studied allodapine species, *Exoneura bicolor*, it is the temporal order in which females emerge that is critical to reproductive dominance (Schwarz and O'Keefe, 1991). The first female(s) to emerge are the first ones to activate their ovaries, and apparently they repress ovarian activity in their nestmates.

3.13.3.3.3.1. The primitively social bumblebees In comparison to the aforementioned bees, where females still can facultatively adopt a solitary or social strategy, sociality in the bumblebees is obligatory and colonies can become quite large. The Bombini are large bees adapted to nesting in colder climates. Virgin queens emerge in autumn, mate, and hibernate before founding a new nest in spring. These queens are long-lived and survive for the entire seasonal nest cycle. The first brood emerging in early spring consists of few rather small females (workers) that aid their mother in rearing the subsequent batches of exclusively female brood. Workers can vary considerably in size, and there is even slight overlap with queens in size–frequency distributions. During midsummer, the queen starts to lay haploid (male-producing) eggs, in addition to further female eggs. Soon after this "switch point," a few workers of high social rank also begin to lay (haploid) eggs, contributing to male production. The onset of worker reproduction has been termed the "competition point" (Duchateau and Velthuis, 1988), and marks an important incision in the colony life cycle, since from this point onwards social integration deteriorates. By the end of the season, the colony produces large queens, which disperse and subsequently mate and hibernate. These components of the annual nest cycle have best been studied in *Bombus terrestris* (Röseler, 1985), where concentrated efforts in breeding and colony-rearing programs have been made to introduce this species successfully as a pollinator in greenhouses.

Although females produced before the competition point can attain a relatively large size, they never become queens (Cnaani *et al*., 1997; Cnaani and Hefetz, 2001). This inhibition of queen production during the early stages of the colony cycle can theoretically be attributed either to "nutritional castration," that is feeding of less or lower-quality food to these larvae, or to a direct inhibitory effect from the egg-laying queen (Röseler, 1970). Long-term videorecording of feeding acts, larval food analysis, and manipulation of feeding frequency (Ribeiro, 1999; Ribeiro *et al*., 1999; Pereboom, 2000; Pereboom *et al*., 2003) have now established clearly that nurse bees do not manipulate the larvae in their feeding program, but rather respond to hunger signals given off by the larvae. So, it is obviously the intrinsic feeding program of the larvae themselves that is already defined during the early larval instars.

The decision as to which feeding program the larvae will adopt has been attributed to a queen signal, which inhibits larvae from developing into queens before the competition point in the colony cycle (Röseler, 1974). Although supposed to be a primer pheromone (Röseler *et al*., 1981), its source and nature have not yet been determined unambiguously (Bloch and Hefetz, 1999b). Meticulous studies on the endocrine response elicited in the larvae pinpointed the first and early second larval instar as the critical window for this queen signal (**Figure 9**). From the fifth day of the second instar, pre-competition-point larvae show markedly reduced levels of JH synthesis (Cnaani *et al*., 1997), as well as lower JH titers (Cnaani *et al*., 2000b), when compared to queens. This response in the CA correlates with caste-specific differences in the ecdysteroid titer (Hartfelder *et al*., 2000), indicating a synergistic interaction of the CA and prothoracic gland during the second and third larval instars. Interestingly, these hormone titer differences vanish during the feeding phase of the last larval instar, when both castes exhibit low JH and ecdysteroid titers (Cnaani *et al*., 2000b; Hartfelder *et al*., 2000). Hormonal caste differences make their reappearance during the spinning and prepupal stages (Strambi *et al*., 1984). Yet at that point titers do not exhibit quantitative modulation but only a temporal one in the position of the prepupal JH and ecdysteroid titer peaks (**Figure 9**).

Social conditions, especially the phase in the colony cycle, have a strong impact on the endocrine system, and thus on the switch from worker to queen development in the individual larvae. This was demonstrated when comparing JH release rates in larvae that were reared shortly before and shortly after the competition point (Cnaani *et al*., 2000a).

This cascade from pheromonal effects on the feeding program to associated endocrine events in

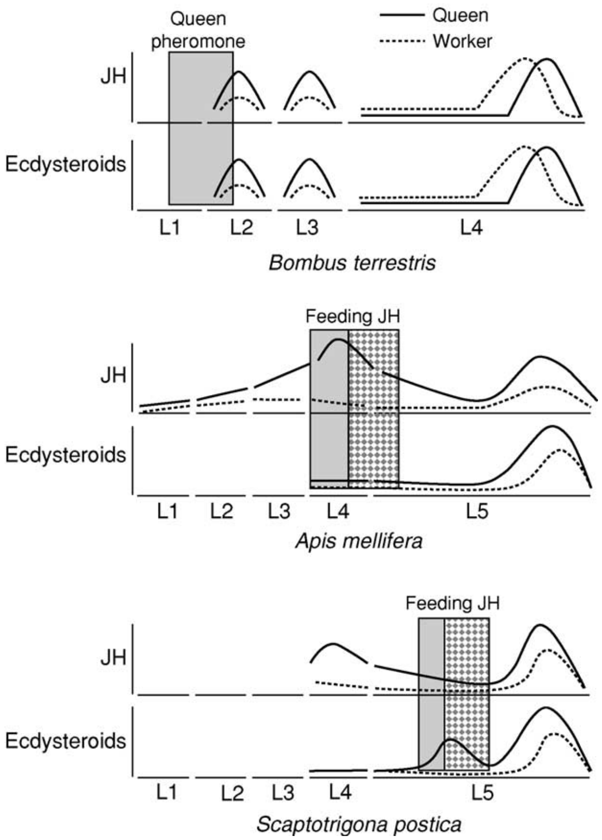

Figure 9 JH and ecdysteroid titer profiles in critical stages of caste development of the primitively eusocial bumblebee, *Bombus terrestris*, and the highly eusocial bees *Apis mellifera* and *Scaptotrigona postica*. In the primitively eusocial bumblebee, prospective queen and worker larvae differ in their JH and ecdysteroid titers during the early larval stages. Exposure during a critical period (shaded bar) to a repressor pheromone emitted by the egg-laying queen affects the hormone titers in the subsequent larval instars (L2 and L3). In the last larval instar (L4), the differences in hormone titers between queens and workers vanish and only a temporal shift in titer peaks is observed in the prepupal stage. In contrast, in the highly eusocial bees, *Apis mellifera* and *Scaptotrigona postica*, the JH and ecdysteroid titers exhibit marked differences during the late larval stages. In *Apis mellifera*, the major JH titer differences overlap with the nutritional switch from royal jelly to worker jelly in the fourth and early fifth instar (shaded bar). In *Scaptotrigona postica*, queen development is dependent on a prolonged feeding period (shaded bar) in the fifth instar. Both in *Apis* and in *Scaptotrigona*, these critical stages overlap with a JH-sensitive period (dotted bar). Morphological differences between queens and workers make their appearance in the highly eusocial bees but not in bumblebees. In the latter, queens and workers differ mainly by size and in some physiological parameters. The expression of morphological caste differences thus appears to depend on sustained hormone titer differences in the last larval instar. Hormone titer profiles for *B. terrestris* were compiled from data by Strambi, A., Strambi, C., Röseler, P.-F., Röseler, I., **1984**. Simultaneous determination of juvenile hormone and ecdysteroid titers in the hemolymph of bumblebee prepupae (*Bombus hypnorum* and *B. terrestris*). *Gen. Comp. queen/worker differentiation does not necessarily represent a generalized chain of events in bumblebee caste polyphenism. Of the few comparative studies that have been carried out on other bumblebee species, the most noteworthy ones were on *B. hypnorum*, which was chosen for its different strategy in provisioning the larvae (Röseler, 1970). In this species, the queen/worker polyphenism involves a much later critical period. Caste fate is not determined during the early instars as it is in *B. terrestris*; instead, it is the feeding conditions in the last larval instar that appear to be the decisive factor. Yet again, the feeding differences converge in a caste-specific differential response in the endocrine system, and as in *B. terrestris*, the prepupal JH and ecdysteroid titer peaks of *B. hypnorum* workers precede the corresponding peaks in queens (Strambi *et al*., 1984).

As mentioned above, adult bumblebee workers and queens differ in size – despite some overlap in the bimodal size frequency distribution – and to some extent in their physiology, mainly in their energy metabolism (Röseler and Röseler, 1986), yet not in their capacity to lay eggs. Even in the presence of the queen, a considerable percentage of *B. terrestris* workers can exhibit signs of ovary activation. However, fewer than 40% of the workers complete oogenesis and also these latter ones do not lay eggs before the switch point in the colony cycle (Duchateau and Velthuis, 1989). Until this time point, egg-laying in workers is presumably inhibited by a queen-produced pheromone. The first studies pointing out a correlation between a queen inhibitory signal, JH production, and egg-laying by workers were carried out by Röseler (1977) and Röseler

and Röseler (1978). Reproductive workers had elevated CA activity and JH titer, relative to non-"activated" workers, and the queen inhibition of worker egg-laying could be overcome by topical application of JH. A closer look revealed the existence of a dominance hierarchy within the worker caste in both queenright and queenless colonies. Dominant workers exhibit agonistic behavior towards lower-ranking workers, resulting in decreased CA activity and inhibition of egg-laying in the latter (Röseler *et al*., 1981; Doorn, 1987).

More recent studies further explored the apparent dichotomy in worker reproduction, that is, reproduction in the absence of the queen, and worker reproduction after the competition point, yet in the presence of the queen. In small groups of queenless workers, a dominance hierarchy soon becomes established, which is reflected in elevated JH titers in the high-ranking egg-laying workers. The sequence in the response to queen removal was documented when following JH synthesis, JH titer, ecdysteroid titer, and egg development during the first 6 days in groups of queenless as compared to queenright workers (Bloch *et al*., 1996; Bloch *et al*., 2000a, 2000b). Levels of JH synthesis and JH titer were significantly elevated in workers by 3 days after removal of the queen, followed by a similar increase in ecdysteroid titer and terminal oocyte length at day 6 (**Figure 10**). This enhancement in JH release rates occurred independently of the colony cycle, that is, JH release was equally elevated in workers made queenless before and after the competition point (Bloch *et al*., 1996), giving little support to the hypothesis that (queenright) worker reproduction might be related to a decrease in queen inhibition after the competition point. Yet there was a strong correlation with worker age, since it was mainly the older workers that had elevated levels of JH release, and thus became dominant egg layers, both in queenless groups and in post-commitment-point colonies. Thus, the absence of the queen is not the *sine qua non* for worker reproduction, since individually kept workers did not initiate egg-laying and, correspondingly, maintained a low JH titer (Larrere and Couillaud, 1993). In accordance with previous studies on worker dominance hierarchies, summarized by Röseler and van Honk (1990), it appears to be the high-ranking (older) workers that inhibit JH synthesis and ovary activation in lower-ranking (younger) workers (Bloch and Hefetz, 1999b). If so, worker reproduction should be inhibited differentially during the two main phases of colony development, that is, prior to the competition point it is a queen inhibitory signal that suppresses egg development in high-ranking workers, and this acts synergistically with an inhibitory effect of dominant workers on ovary activation in the lower-ranking workers. After the competition point, it is primarily the high-ranking workers that control egg production in their

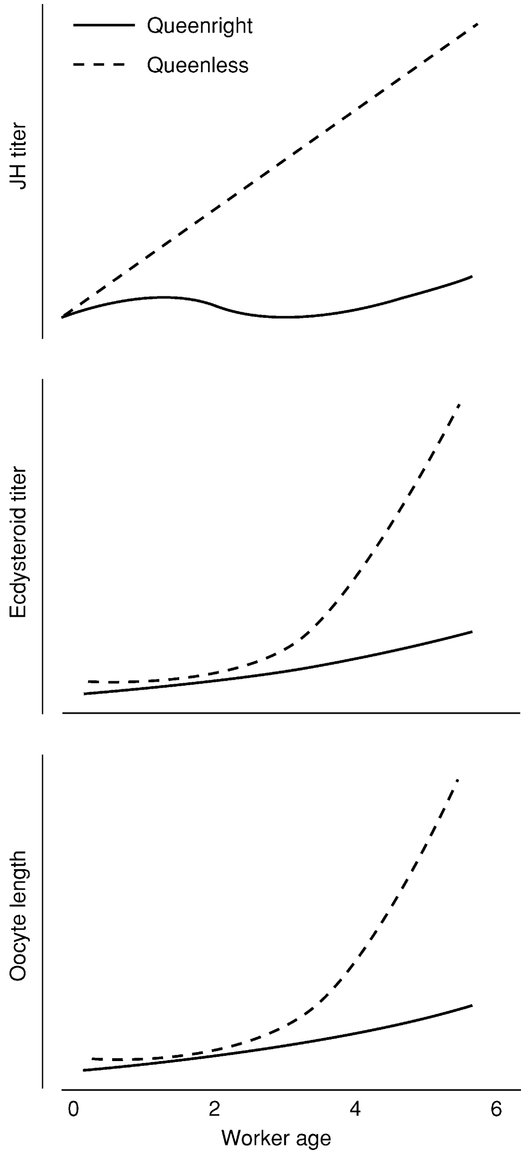

Figure 10 Queen effect on worker reproduction in *Bombus terrestris*. Removal of the queen elicits a rise in the JH titer of adult bumblebee workers, and subsequently results in a correlated response in oocyte growth and hemolymph ecdysteroid titer. This association strongly indicates that JH is involved in worker fertility, and that the presence of an egg-laying queen represses CA activity. (Modified from Bloch, G., Borst, D.W., Huang, Z.Y., Robinson, G.E., Cnaani, J., *et al*., **2000a**. Juvenile hormone titers, juvenile hormone biosynthesis, ovarian development and social environment in *Bombus terrestris*. *J. Insect Physiol. 46*, 47–57; and Bloch, G., Hefetz, A., Hartfelder, K., **2000b**. Ecdysteroid titer, ovary status, and dominance in adult worker and queen bumble bees (*Bombus terrestris*). *J. Insect Physiol. 46*, 1033–1040.)

nestmates. Both of these inhibitory signals appear to be mediated through the neuroendocrine axis, particularly via JH release. The elevated ecdysteroid titer observed concomitantly with progressive oogenesis (Bloch *et al.*, 2000b) should be interpreted primarily as a consequence of JH-stimulated ovary activation. However, one cannot exclude an ecdysteroid-mediated synergistic feedback effect on dominance (just as in the *Polistes* wasps) (see Section 3.13.3.3.1).

Surprisingly, the strong correlation observed between JH titer and ovary activation in workers (Bloch *et al.*, 2000b) was not as striking in queens, which have lower JH titers than egg-laying, queenless workers (Larrere *et al.*, 1993; Bloch *et al.*, 2000a). A high JH titer is therefore not an absolute requirement for egg production, at least in queens, and may be more related to a combination of dominance status and egg production in the workers than with queen reproduction. In fact, ecdysteroids may play a more important role in queen reproduction than in worker reproduction, as evidenced by the elevated ecdysteroid titers in overwintered queens, as compared to virgin queens and queenless workers (Bloch *et al.*, 2000b). Thus it seems that in bumblebees we are confronted with the dual role of JH and ecdysteroids in female reproduction.

3.13.3.3.3.2. The highly social honeybees and stingless bees Honeybees (Apini) and their sister group Meliponini, colloquially refered to as stingless bees, have been companions of mankind for almost as long as locusts. Their origin and social organization have been narrated in picturesque myths, and their biology is a well-represented element in ethnobiology. The common themes to these myths are the nature of social integration and the origin of the differences in form and function between queens and workers. One of the main difficulties in explanations for queen/worker dimorphism, both for myths and the modern scientific approach, resides in the identification of the mode of action of the initial triggers in caste development.

As in most social insects, this is a problem of larval nutrition. In the honeybees, larvae are fed continuously during larval development, and during the early larval instars, both queen and worker larvae receive mainly a glandular proteinaceous secretion (royal jelly). In the fourth and fifth larval instar this type of food is provided in large quantities only to queen larvae, whereas worker-destined larvae are fed a mixture of glandular secretions, honey, and pollen. Apart from the switch in diet, worker larvae are also visited much less frequently than queen larvae (Beetsma, 1985). Attempts to identify specific queen-determining factors in royal jelly resulted in a partial purification of labile factors (Rembold *et al.*, 1974b), but did not provide unequivocal evidence for a "queen determinator." Rather, they suggest the necessity for a balanced diet.

This view is also consistent with results of larval food analyses in stingless bees (Hartfelder and Engels, 1989), which do not feed their brood progressively but rather mass provision the brood cells shortly after they are built. Due to mass provisioning of the brood cells and lack of further interaction of worker bees with the developing brood, other than regulation of the colony microclimate, there is no evidence for a nutritional switch in the stingless bees that could serve as a signal for queen/worker development. In the majority of the stingless bee species, that is those belonging to the highly diverse trigonine genera, queen development depends on the quantity of larval food provided to the larvae, and this is reflected in the size of the cells. Large queen cells containing two- to threefold more larval food than the worker cells are often built at the margins of the horizontal brood combs (Engels and Imperatriz-Fonseca, 1990), or can result from the fusion of two brood cells sitting on top of one another, thus providing a larva with a second portion of larval food. This strategy of queen production is also observed in the context of emergency queen rearing in some species, that is when a colony has lost its queen (Faustino *et al.*, 2002).

An exception to the queen/worker-determining mechanism by modulation of larval food quantity is the genus *Melipona*. Their brood cells are of equal size, irrespective of whether queens, workers, or males are reared within them. The fact that up to 25% of the female brood can be queens led Kerr (1950) to propose the hypothesis of a genetic predisposition with a two-locus, two-allele system, in which only double heterozygotes can become queens. Yet even in this system, larval food quality has a modulating effect on caste differentiation (Kerr *et al.*, 1966), since maximal proportions in queen production are only observed in strong colonies that have sufficiently large stocks of honey and pollen. Under suboptimal conditions the proportion of queens in the female brood is well below 25%. Even though frequently contested and still awaiting final support from genetic analyses and identification of the proposed loci, this hypothesis has a higher heuristic value than an alternative hypothesis that attributes "self-determining" capacity to the larvae (Ratnieks, 2001). Irrespective of the distinct modalities in initial triggers – nutritional switch in honeybees, large food quantities in trigonine bees, or a genetic predisposition in *Melipona*

species – all these inputs eventually converge in caste-specific activity patterns in the endocrine system which governs subsequent differentiation events in the target tissues.

3.13.3.3.3.2.1. The endocrine regulation of caste development in honeybees This endocrine cascade has been best explored in the honeybee. JH application experiments carried out in the 1970s indicated a prominent role for JH in caste development, and established a critical window for its action in the fourth and early fifth larval instar (Rembold *et al.*, 1974a; Dietz *et al.*, 1979; and further references in Hartfelder, 1990). Subsequent analyses of endogenous JH titers by specific radioimmunoassays (RIAs) and highly sensitive GC/MS corroborated these experimental JH effects, revealing a marked difference in JH titers between queen- and worker-biased larvae (**Figure 9**) during larval, prepupal, and the late pupal stages (Rembold, 1987; Rachinsky *et al.*, 1990; Rembold *et al.*, 1992). From these meticulous JH titer analyses it was possible to ask how the JH titer differences may be generated, and how these may affect caste-specific differentiation processes. Analyses of JH biosynthesis and release rates by a radiochemical assay revealed a markedly elevated CA activity in prospective queen larvae between the fourth and the early fifth larval instar (Rachinsky and Hartfelder, 1990), proving that the JH titer differences are primarily a result of differential CA activity (rates of JH degradation were generally low in honeybee development) (Mane and Rembold, 1977).

An interesting facet was the finding that the terminal steps in JH biosynthesis are the critical ones for the differential JH release rates in early fifth instar queen and worker larvae (Rachinsky and Hartfelder, 1991; Rachinsky *et al.*, 2000). Blocking the terminal steps from farnesoate to JH III is an efficient means to generate and guarantee low JH titers in worker larvae during the fourth and early fifth instar (see **Chapter 3.7**). Furthermore, since this block is reversible, as required to generate the elevated JH titers in prepupae (Rachinsky and Hartfelder, 1990, 1991), the *ortho*-methylfarnesoate transferase and the JH-epoxidase are candidate targets for allatoregulatory factors. Radiochemical assays on the CA of worker larvae showed that the *Manduca sexta* allatotropin can stimulate JH synthesis in honeybees in a dose-dependent manner, yet does not overcome the block of the terminal steps (Rachinsky and Feldlaufer, 2000; Rachinsky *et al.*, 2000). Corpus allatum regulation becomes more complex considering that a set of peptides from the brain and suboesophageal ganglion (Rachinsky, 1996) and also biogenic amines, especially serotonin (5HT) and octopamine (Rachinsky, 1994), may modulate JH biosynthesis to generate the observed caste-specific profile.

This search for allatoregulatory factors represents an upstream walk to close the gap between the initial nutritional signal that induces caste development and its translation into an endocrine response. In addition to the identification of the respective players, this also requires mapping of the structural pathways involved in such signal processing and transmission. The only pathways mapped in this context are the serotonergic system (Boleli *et al.*, 1995; Seidel and Bicker, 1996) and the stomatogastric nervous system (Boleli *et al.*, 1998). Immunocytochemical mapping of serotonergic neurons in honeybee larvae and pupae revealed an apparent heterochrony in their development. Whereas serotonergic neurons in the ventral ganglia exhibited a seemingly mature architecture already in the larval stages, 5HT-neurons in the brain matured only during late pupal–adult development (Boleli *et al.*, 1995). These results preclude an allatoregulatory function for protocerebral 5HT-neurons during preimaginal development. Instead, the detection of immunoreactive cell bodies in the vicinity of the CA, close to their connection to the nervi corporis cardiaci III, implicates the stomatogastric nervous system in the modulation of CA activity. Since the stomatogastric nervous system provides a direct link between sensory cells for food quality in the labral region of honeybee larvae (Goewie, 1978), food-intake-mediating neurons of the stomatogastric nervous system, and the retrocerebral endocrine complex (Boleli *et al.*, 1998), the nutritional switch information could certainly take this (alternative) pathway. Despite the considerable progress on this subject, the information on perception and processing of the nutritional switch signal in bees is still rudimentary and remains a major “black box” in our understanding of events upstream of the caste-specific endocrine response.

One of the downstream effects resulting from differences in JH titers between honeybee queen and worker larvae involves the endocrine system itself, as an internal circuit between the CA and the prothoracic glands. The latter were identified as loose agglomerates of cells projecting from the larval foregut to the retrocerebral complex (Hartfelder, 1993), and their activity pattern closely reflects the ecdysteroid titer in the last larval instar (Rachinsky *et al.*, 1990). The ecdysteroid titer, with makisterone A as the main compound, is low at the beginning of the last instar (**Figure 9**), and exhibits a marked peak during the prepupal stage in both

castes. Caste-related differences in the larval ecdysteroid titer are evident in the cocoon-spinning phase, with an earlier increase in queens than in workers. Mimicking a queenlike JH titer by JH application during the fourth to early fifth instar resulted in an earlier increase in prothoracic gland activity (Rachinsky and Engels, 1995). This positive interaction between JH titer and prothoracic gland activity may involve a prothoracicotropic hormone (PTTH)-like factor, which was detected immunohistochemically in honeybee brain sections (Simões *et al.*, 1997).

Alternatively, JH could stimulate ecdysteroid synthesis and release directly in the prothoracic glands, as demonstrated by *in vitro* assays exposing these glands to different doses of methoprene (Hartfelder and Engels, 1998). The positive action of JH on the ecdysteroid titer in worker larvae seems to be restricted to the larval–pupal transition, since JH application to pupae inhibits and retards the formation of the large pupal ecdysteroid peak (Zufelato *et al.*, 2000), which also consists mainly of makisterone A (Feldlaufer *et al.*, 1985).

In terms of target tissues, it is the ovary that has received most attention, as it best reflects the functional caste differences. A typical queen ovary consists of 180–200 ovarioles, whereas a worker ovary most often contains between two and four ovarioles, rarely exceeding 12 of these serial units. These differences arise primarily during the final larval instars, even though some of the differentiation steps are already visible by the second instar (Dedej *et al.*, 1998; Reginato and Cruz-Landim, 2001). Caste-specific differentiation of the ovary consists primarily of a reduction in ovariole number in the worker caste, from an initially equal number of ovariole anlage in the two castes – generally over 150 anlagen per ovary in the fourth instar – to the final set of ovarioles at pupation. Histologically, this process is marked by a reduced number of rosette-like cystocyte clusters in early fifth instar worker ovarioles, and a large number of autophagic vacuoles (Hartfelder and Steinbrück, 1997).

As shown by BrdU (bromo deoxy uridine) labeling, the reduced number of cystocyte clusters is not due to a diminished mitotic activity in the ovaries of worker larvae (Schmidt Capella and Hartfelder, 1998), but rather results from a disintegrating actin cytoskeleton in the germ cells (Schmidt Capella and Hartfelder, 2002). During the transition from the fourth to the fifth larval instar (which exactly coincides with the critical window for JH), actin loses its affinity to spectrin and forms large unstructured aggregates in the germ cell region of worker ovarioles. It is exactly at this location that shortly thereafter signs of apoptotic cell death appear. These degradative processes initiated by actin–spectrin dissociation could be prevented by a single topical JH application to late fourth instar workers (Schmidt Capella and Hartfelder, 1998, 2002). Even though these analyses permit us to pinpoint a cell biological target for JH in an important caste differentiation process, we cannot yet establish whether JH acts directly on the affinity of actin to spectrin, or whether this results from a transcriptional effect on factors that mediate the interaction between these cytoskeletal components.

3.13.3.3.3.2.2. Honeybee caste development: genomic studies As in functional genomics in general, complex transcriptional regulation can also be expected to be a key factor in our comprehension of caste development, and in this respect, the honeybee stands out as a model organism amongst the social insects. The early studies on mRNA differences between queen and worker larvae (Severson *et al.*, 1989) have gained considerable depth and impetus from powerful molecular methods, such as differential display (Corona *et al.*, 1999; Hepperle and Hartfelder, 2001) and suppression–subtractive hybridization protocols (Evans and Wheeler, 1999). These efforts, and particularly the coupling of high-throughput sequencing of expressed sequence tags (ESTs) to powerful clustering algorithms (Evans and Wheeler, 2000) represent a major breakthrough and turning point in our understanding of the complexity of caste differentiation. Two dichotomies emerge from cluster analyses of these gene expression screens (**Figure 11**). The first one is a dichotomy in gene expression patterns for early versus late larval stages, independent of caste. The second one is a queen–worker dichotomy in gene expression that is initiated in the late larval stages (Evans and Wheeler, 2001). Many of the genes that exhibited caste-specific expression encode metabolic enzymes, and thus represent an early response to the nutritional switch occurring during the fourth larval instar.

Whereas these results give us a view of the formidable complexity in genomic regulatory changes that take place during caste development, they still leave open the fundamental question as to the role of JH and ecdysteroids in this process. In fact, they only permit *post hoc* inference on hormone effects by correlations of hormone titers with the observed gene expression patterns. Direct evidence for hormone effects in caste differentiation and a glimpse into their mode of action, so far, has only been obtained for ecdysteroids in the context of ovary development. Two-dimensional analysis of protein

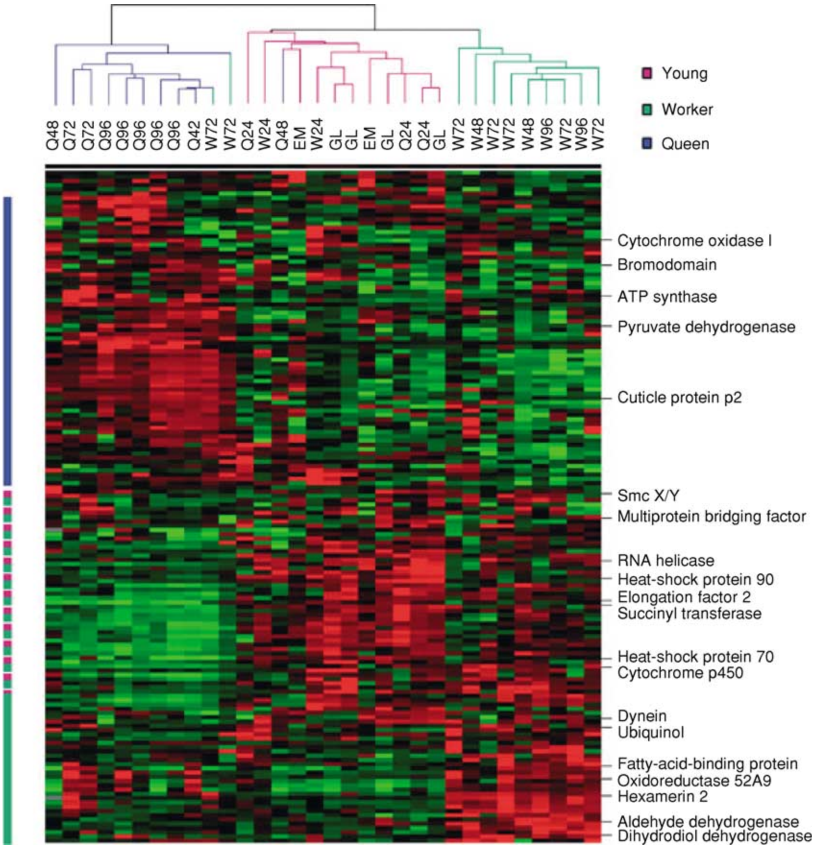

Figure 11 Microarray analysis of complex gene expression patterns in caste development of the honeybee. Clusterization revealed three sets of developmentally coregulated genes. The first cluster is characterized by genes exhibiting higher expression levels in young (still bipotential) larvae vs. older larvae. The second cluster joins genes which are higly expressed in worker larvae, particularly in the last larval instar, and the third cluster represents genes with elevated expression levels in fifth instar queen larvae. (Reproduced with permission from Evans, J.D., Wheeler, D.E., **2000**. Expression profiles during honeybee caste determination. *Genome Biol. 2,1*, 6 pages, available online http://genomebiology.com; USDA; Genome Biology is an Open Access Journal.)

synthesis patterns in larval ovaries exposed to physiological doses of makisterone A *in vitro* revealed a suppressive effect of this hormone on two low molecular weight proteins (Hartfelder *et al*., 1995) and reflected *in vivo* changes in protein synthesis that can be attributed to the caste-specific ecdysteroid titers. A subsequent differential display polymerase chain reaction (PCR) analysis of gene expression in ovaries of honeybee worker larvae showed that makisterone A has a repressive effect on the transcription of numerous genes, including transcription factor homologs, such as *FTZ-F1* and a *cut* homolog (Hepperle and Hartfelder, 2001), as well as on factors involved in cell signaling and in metabolic enzymes. As in the above-mentioned gene expression screens, metabolic enzymes constitute an important group in the ecdysone-responsive genes in the honeybee. One of these, a short-chain reductase/dehydrogenase, has been fully sequenced permitting a detailed analysis of its ecdysone regulated expression *in vivo* and *in vitro* (Guidugli *et al*., 2004).

3.13.3.3.3.2.3. Honeybee reproduction and division of labor The high rate of egg production in the honeybee queen requires an enormous production of vitellogenin by the fat body. In contrast to most insects (see **Chapter 3.9**) hormonal regulation of vitellogenin expression in honeybees is rather puzzling. Experiments with JH application and allatectomy, and also JH titer analysis, seemed to rule out any role for this hormone in the regulation of the vitellogenin titer, which exhibits a tremendous increase during the first days after emergence of the young queen from its brood cell (Engels, 1974; and other references cited in Hartfelder and Engels, 1998). Recent investigations, however, showed that the rising JH titer in late pupal development of queens and the slight increase occurring during the first 24 h in adult workers coincide with the appearance of vitellogenin in hemolymph. Further, application of the JH analog pyriproxifen caused a precocious increase in vitellogenin levels in late pupae of both castes (Barchuk *et al*., 2002).

In contrast to JH, no apparent role in reproduction and division of labor could so far be attributed to ecdysteroids in female honeybees. Except for a transient small peak early in the adult life cycle, ecdysteroid titers fluctuated at basal levels, independent of caste, reproductive status, and colony social conditions (Hartfelder *et al.*, 2002). This is all the more striking when considering that considerable levels of ecdysteroids were detected in the ovaries of adult queens (Feldlaufer *et al.*, 1986). This apparent lack of function for ecdysteroids in the reproductive physiology of highly eusocial bees, when compared to the more primitively social bees or wasps, however, may need to be reviewed in new light. Real-time PCR analysis utilizing primers directed against the recently described honeybee vitellogenin cDNA (Piulachs *et al.*, 2003) detected vitellogenin expression already during larval stages (Guidugli and Simões, personal communication), that is, during a period when ecdysteroids are primarily responsible for synchronizing and pacing development. Another novel molecular tool, namely gene silencing by injection of double-stranded RNA, should also soon shed new light on the long-discussed connection between vitellogenin, lifespan regulation, and hormonal regulation. Promising results utilizing such a strategy have recently been reported from RNA interference experiments with vitellogenin (Amdam *et al.*, 2003b).

Caste and reproduction in the highly eusocial insects are intimately related to lifespan, and recent studies have now provided evidence that vitellogenin production is directly implicated in honeybee lifespan. Besides being of interest to gerontology (Page and Peng, 2001), these findings also stimulated novel models that reconsider division of labor in honeybee colonies as an aspect integral to reproduction (Amdam and Omholt, 2002, 2003). In the center of these models stands the regulation of the vitellogenin titer during the adult lifespan of honeybee workers, since vitellogenin is not only an essential protein for oogenesis but also is a major zinc transporting protein, and as such, is involved in the delay of aging. Since JH represses vitellogenin synthesis in fat body preparations (Engels *et al.*, 1990), and thus explains the decrease in vitellogenin observed in older bees (Engels, 1974), zinc levels and hemocyte quality were also shown to decrease as honeybee workers age and start to perform high-risk tasks (Amdam and Omholt, 2002; Amdam, personal communication). These studies attribute a new functional role to the high vitellogenin titers in nurse bees, which for a long time have been considered an enigmatic by-product of supposedly leaky hormonal regulation. The detection of putative vitellogenin receptors on the larval food-producing hypopharyngeal glands of nurse bees suggests that vitellogenin, in fact, retains a reproductive function also in honeybee workers, yet instead of being incorporated into eggs, it is converted into larval food (Amdam *et al.*, 2003a).

The hormonal regulation of vitellogenin synthesis thus also consitutes an integral element in the division of labor among honeybee workers, that is, in the sequence of tasks that they perform during their short adult lifespan. Since hormonal regulation of division of labor in honeybees has been the subject of excellent recent reviews (Fahrbach, 1997; Robinson and Vargo, 1997; Page and Peng, 2001; Bloch *et al.*, 2002; Page and Erber, 2002), this topic is being considered only briefly. Early experiments by Jaycox (1976) indicated a straightforward role of JH in the division of labor, as JH application to young bees promoted a precocious switch from activities within the nest, especially brood care, to foraging activities (typical of older workers). Subsequent analyses of JH titers and CA activity confirmed this hypothesis, showing that rates of JH synthesis and hemolymph JH titers in worker bees strongly increase as the bees age and become foragers (Huang *et al.*, 1991; Robinson *et al.*, 1991, 1992). Recent studies revealed that seasonal factors (Pearce *et al.*, 2001) and the genetic constitution of a worker bee also have a strong effect on behavioral development and task preference (Giray *et al.*, 1999, 2000). The most surprising finding was, however, that allatectomy performed on newly emerged workers did not abolish but only retarded by a few days the behavioral switch from nursing to foraging activities (Sullivan *et al.*, 2000). Interestingly, this retardation effect could be prevented by a topical application of the JH analog methoprene.

Age-related polyethism, the performance of different tasks by bees of different age, can now also be addressed at the molecular level. Expression analyses in the adult honeybee brain spearheaded by Whitfield *et al.* (2002) and Kucharski and Maleszka (2000) resulted in the establishment of microarray slides for genomic analyses of age polyethism and division of labor, which may help to elucidate the still enigmatic role of JH in aging and division of labor.

3.13.3.3.3.2.4. Hormonal control of caste development and reproduction in stingless bees The stingless bees are not only the sister group to the monogeneric tribe Apini, but are also represented by an enormous number of species (Camargo and Pedro, 1992). Thus, they supply us with ample material for evolutionary insights into caste polyphenism and

reproduction in highly social bees. As aforementioned, it is the nutritional conditions that, in this group also, serve as initial trigger in the divergence of the queen/worker developmental pathways, even though in the genus *Melipona* there is strong evidence for a genetic predisposition to caste fate (Kerr, 1950).

As in the honeybee, the initial investigations on the role of hormones in stingless bee caste differentiation all relied on JH application experiments. These comparative investigations on different species of stingless bees (Campos *et al*., 1975; Campos, 1978, 1979; Buschini and Campos, 1994; Bonetti *et al*., 1995) established the spinning stage of the last larval instar as the critical phase for JH-dependent induction of queen development. These findings subsequently received support from investigations on CA activity and JH titer measurements in *Scaptotrigona postica* (Hartfelder, 1987; Hartfelder and Rembold, 1991). Except for clear JH titer differences between queen- and worker-destined larvae during the spinning stage, further caste-related JH titer differences also became apparent during the penultimate and early last larval instar, as well as at the end of pupal development (**Figure 9**). These characteristics demonstrate the close similarity between stingless bees and the honeybee with respect to developmental profiles of JH titers, despite the fact that the critical window for JH-induced queen development and, thus, the divergence of queen/worker pathways, occur much later in stingless bees than they do in the honeybee (Hartfelder, 1990). This may reflect a strong input from the differences in larval nutritional programs in the two groups noted previously. Consequently, queen development in the trigonine species takes longer than worker development, with the opposite being true for honeybees and the genus *Melipona*. These differences in nutritional programs between the three groups (*Apis, Melipona*, Trigonini) are reflected in larval and especially pupal ecdysteroid titers (Hartfelder and Rembold, 1991; Pinto *et al*., 2002), suggesting a correlated regulation of caste development by JH and ecdysteroid in all groups of highly social bees.

The high species diversity in the stingless bees, their variation in colony size, nesting sites, and the large number of further aspects in social lifestyles obviously provide material for variation on the basic theme of caste development, reproduction, and division of labor, and possible hormonal regulation therein. An important difference between honeybees and stingless bees lies in the degree of morphological differences between the sexes and castes. The males of stingless bees are morphologically much more similar to workers than they are to queens (Kerr, 1987, 1990), even though growth rules for the different morphogenetic fields along the body axes appear to be adjusted rather independently (Hartfelder and Engels, 1992).

A striking phenomenon calling for functional explanations is the strong variation in queen size in some species. The occurrence and reproductive performance of miniature queens were studied closely and compared to normal-sized queens in *Schwarziana quadripunctata* and *Plebeia remota* (Ribeiro and Alves, 2001; Ribeiro *et al*., 2002), indicating functional differences in reproductive performance related to colony conditions.

Since monopolization of reproduction by the queen is a key element in the social evolution of bees, the large variation in reproductive activities by the workers among stingless bee species can provide insight into different evolutionary solutions to the queen–worker conflict over reproduction. Worker oviposition can take two forms: trophic eggs that are laid shortly before the queen oviposits, and reproductive eggs that are laid after a queen's oviposition. Trophic eggs are unfertilized eggs that are specially produced as nutrition for the queen to maintain her high reproductive rates. Worker vitellogenin is thus directly shunted into egg production by the queen. Since the production of (trophic) worker eggs is clearly in the interest of the queen, she does not discourage worker production of these unfertilized eggs. It is therefore not surprising that worker-produced eggs can make a significant contribution to male production in a colony (Engels and Imperatriz-Fonseca, 1990, and references cited therein). Some species, such as *Frieseomelitta varia*, have opted for an entirely different solution to this conflict, as their workers are sterile, due to the complete degeneration of their ovariole anlagen during pupal development (Boleli *et al*., 1999, 2000).

The involvement of hormones in the regulation of reproduction and division of labor in adult stingless bee queens and workers has only been investigated marginally; and so far, there is only negative evidence to this end in *Melipona quadrifasciata*. As in the honeybee, ecdysteroids do not seem to play any role in queen or worker reproduction in *M. quadrifasciata* (Hartfelder *et al*., 2002), and JH titer analyses by RIA also did not provide any lead that could imply the role of this hormone in female reproduction or division of labor (Santana and Hartfelder, unpublished data).

3.13.3.3.4. Caste in polyembryonic wasps Polyembryony represents a dramatic divergence from developmental regulation in insects. It requires a reorganization of axis and positional information

in the myriads of embryos forming after syncytial cleavage in the egg of parasitic wasps, where it has been studied extensively in *Copidosoma floridanum* (review: Strand and Grbic, 1997). While it represents a highly adaptive mode of reproduction for the tiny parasitoid female to colonize a valuable yet perishable resource by laying a single egg into an insect host larva, the more fascinating is the observation that different morphs can arise from these embryos. Most embryos develop into reproductive larvae that undergo pupal and adult molts, yet a small number of embryos develop into precocious larvae that form a sterile soldier caste whose function is to manipulate the sex ratio of reproductive larvae and to protect the brood from other parasites that attack the same host (Cruz, 1981; Strand *et al*., 1990; Grbic *et al*., 1992).

As in the equally clonal aphids, regulatory mechanisms governing divergence of developmental pathways into precocious soldier larvae and normal reproductive ones are not well understood. The host endocrine milieu is clearly a prime factor that affects and synchronizes larval development and metamorphosis of the parasite with that of the host, and a combination of *in vivo* and *in vitro* experiments suggests that host ecysteroids, but not JH, are important factors in caste development of these wasps (Strand and Grbic, 1997). To exert their effects, however, prospective soldier and normal larvae must have acquired different degrees of competency to respond to the circulating host hormones since, a priori, the two phenotypes should be exposed to the same endocrine milieu.

What regulates the differential acquisition of competency in *C. floridanum* embryos in response to host ecdysteroids is still unclear. Evidence from paedogenetic gall midges, however, may provide a lead. Comparative analyses on *ecdysone receptor* (*EcR*) and *ultraspiracle* (*USP*) expression in *Heteropeza pygmea* and *Mycophila speyeri* suggest that the timing or the expression of these genes in the larval ovaries is a critical factor in the life-cycle switch from paedogenesis to metamorphosis (Hodin and Riddiford, 2000; see also **Chapter 3.5**).

3.13.4. Synthesis, Patterns, and Future Directions

In the above sections, we detailed insect polyphenisms and their hormonal regulation in a phylogenetic context to facilitate drawing parallels to general modes of development and reproduction in hemi- and holometabolous insects. Yet a functional perspective would be an equally valid approach. The most common form of polyphenism in hemimetabolous insects is a polyphenism for wing length. The development of wings has played a major role in the extraordinary evolutionary and ecological radiation of insects, and it appears that aspects of this mechanism have proven especially amenable to investigations of the evolution of facultative or polyphenic patterns of wing expression. The switch between winged and wingless developmental pathways most often occurs during a late larval instar, and involves modulation of the JH titer during a critical physiological “sensitive period.”

Aphid phase polyphenism continues to be a great enigma in terms of developmental regulation, and despite considerable progress in this field since the last review in this series by Hardie and Lees (1985), there seem to be more questions than answers. This is especially so with respect to the role of JH, which, in view of present evidence cannot be upheld as the sole – or even the principal – endocrine factor.

In locusts, much of the JH controversy has now been resolved. Phase polyphenism in locusts is undoubtedly a complex phenomenon, and phase transition results from cumulative pheromonal and hormonal signals that act during all life-cycle stages, and across several consecutive generations. Hoppers strongly respond to pheromones and can quickly change their endogenous hormone titers in response to changing population density (Botens *et al*., 1997). In turn, the JH titer during critical periods of larval development, in concert with other hormones, such as the neuropeptide [His^7]-corazonin, is capable of altering phase-specific body coloration (Tanaka, 2000a, 2000b, 2000c). In the adult stages of the life cycle, flight physiology, particularly the adipokinetic reaction, is strongly associated with phase (Dorn *et al*., 2000). Pheromones stimulate aggregation and egg-laying behavior and may thus act as a bridge between generations, in concert with phase-specific differences in hormone titers, especially the ecdysteroid content of ovaries and eggs. Such cumulative effects on phase characteristics over the entire life cycle are the hallmark of locust polyphenism, but these can also be found in other groups that exhibit complex life-cycle syndromes (Moran, 1994). Elucidating the architecture of the multiple and synergistic developmental switches remains a challenging task for future work.

In termites, hormonal regulation of caste development has been exploited for pest control, since application of JH analogs can shift the caste-ratio balance towards soldiers (and away from reproductives). Mechanistically, JH has been identified as a competence factor which interacts with ecdysteroids to enhance cuticle deposition after the presoldier and soldier molts (Okot-Kotber, 1983). Furthermore, it

may also be involved in regulating the expression of soldier specific genes, such as *SOL1* (Miura *et al.*, 1999). Establishing such networks of developmental regulation in termite caste morphogenesis will, certainly, require a focus on carefully selected model species in both lower and higher termites. Furthermore, it would be desirable to link such studies to those on hormonal regulation of development in other hemimetabolous species, particularly in cockroaches of the genus *Cryptocerus* which exhibit many similarities to life histories of primitive termites (Nalepa, 1984). Caste polyphenism studies in termites could also profit from developmental programming studies performed on embryonic stages of hemimetabolans, such as the ones performed by Truman and Riddiford (1999) on locusts, which shed new light on the evolution of holometabolous development from hemimetabolan ancestors. In this context, it would be interesting to reanalyze two sets of questions: (1) the relative immaturity of termite larvae, which, especially in the higher termites, need to be cared for by workers and (2) the stationary and regressive molts in lower termites, an astonishing phenomenon in insect metamorphosis which emphasizes the importance of molting events in termite societies.

Wing polyphenism in holometabolans takes two very different forms, that of seasonal wing pattern differences in lepidopterans, and that of wing reduction in ant workers. Wing pattern polyphenism in butterflies is an allelic polymorphism in camouflage in response to predator pressure, which, in its expression, depends on the timing of the pupal ecdysteroid peak (Koch *et al.*, 1996; Brakefield *et al.*, 1998). Winglessness in ant workers, in contrast, is an integral element of caste polyphenism in the Formicidae. It is a result of the shutdown of a gene expression cascade regulating wing disc development (Abouheif and Wray, 2002) in response to embryonic/larval hormone titers.

The focus on *Apis mellifera* as a model organism in research on caste development in social Hymenoptera has certainly been promoted by the honeybee's economic importance, a factor which more recently has also stimulated much of the research on the bumblebee, *Bombus terrestris*. Synthesis and titers of morphogenetic hormones have been monitored throughout the entire life cycle of these insects, and these studies have shown that a correlated modulation of JH and ecdysteroid titers drives caste development during the larval stages (Hartfelder and Engels, 1998). Furthermore, the full cascade from initial environmental triggers through the endocrine response to these triggers, and finally to downstream differentiative processes in target organs, has now been mapped – at least roughly – in honeybees, a process which is now rapidly advancing due to the concentrated efforts in honeybee genomics (Corona *et al.*, 1999; Evans and Wheeler, 1999, 2000, 2001; Hepperle and Hartfelder, 2001).

A general conclusion to be drawn from developmental studies on insect polyphenism is its generally strong dependency on JH; except, of course, for butterfly wing pattern polyphenism where patterning occurs during the pupal period and, consequently, is under ecdysteroid control. Occasionally this may have lead to the oversimplified view that JH may act as a master regulator in generating polyphenism. Rather, the multifaceted appearance that JH makes in this context should be attributed to its pleiotropic general function in insect metamorphosis and reproduction, which facilitated its co-option. Especially in complex life cycles, such as observed in aphids, locusts, and social insects, JH never is the sole factor, but appears integrated in its action with that of other hormones and/or neuropeptides.

Functional genomics has just begun to transform studies of insect polyphenism. Initial efforts have focused on whole-genome, or transcriptome, sequencing, and all efforts thus far have been concentrated on a single species, the honeybee (Beye *et al.*, 1998; Evans and Wheeler, 1999, 2000; Robinson *et al.*, 2002; Tomkins *et al.*, 2002; Whitfield *et al.*, 2002). Even though still at a primitive stage, these genomic studies have already injected new impetus into the field, and led to the application of differential gene expression screens with narrower foci in aphids, locusts, termites, and other social Hymenoptera. Undoubtedly, the near future will see similar screens being performed in a large number of polyphenic species.

We expect two questions to dominate and direct such screens. One is the search for differentially expressed genes in the JH response. This response cascade is still a major question mark in insect physiology, and its elucidation is largely hampered by the lack of unequivocal data on JH receptor(s) (Gilbert *et al.*, 2000; Jones and Jones, 2000). Despite the small amount of genomic information currently available for polyphenic insects, their naturally selected alternative phenotypes may make these insects especially useful tools for identifying and studying the function of JH response cascade elements. Many of these studies may profit from newly established RNA interference protocols (Amdam *et al.*, 2003b).

An alternative approach lies in the specific search for expression patterns of conserved regulatory

genes in relation to alternative pathways in tissue development. The power of this approach has recently been demonstrated in the analyses of interruption points for wing disc development in ants (Abouheif and Wray, 2002). Even more extensively, it has been put to use in the studies of butterfly wing patterns where the link between the expression of patterning genes and EcR, and thus, between hormone titer modulation and eyespot size, has become apparent (Brunetti *et al*., 2001; Koch *et al*., 2003). These studies provide a glimpse into the complexity of regulatory networks underlying polyphenism. What lies ahead in this direction will be a broadened insight into the hormonal modes of action on such genomic regulatory networks. Critical steps towards this end would involve the sequencing of upstream regulatory regions for candidate genes and functional analyses of hormone response elements.

Perhaps the greatest challenge will be to link conceptually the results of such genomic studies with organismic-level studies of physiology, behavior, and ecology. Once again, we expect two questions to remain and/or become predominant. The first one is in the realm of developmental biology and will have to address molecular and cellular mechanisms underlying reaction norms and phenotypic plasticity. Many aspects of phenotypic plasticity in insects can be ascribed to general size-related allometries. These have been mathematically formulated in growth models that assume competition for available nutrients between growing morphogenetic fields (Nijhout and Wheeler, 1994). Such intuitive tradeoffs have, however, not been detected in the only genetically accessible system for this question, that is in *Drosophila* mutants for the insulin receptor antagonist *DPTEN* (Goberdhan and Wilson, 2002). These authors suggest, instead, that tissues may be kept to proportional size by their similarity in response to the evolutionarily conserved insulin-receptor signaling pathway. To our knowledge, the components of this pathway, which could be a major link between reaction norms and developmental mechanisms, have never been studied in relation to insect polyphenisms.

The second question is much broader, and will involve linking evolutionary aspects in the life histories of polyphenic insects to the evolution of regulatory mechanisms underlying the development of alternative phenotypes (West-Eberhard, 2003). This, obviously, is a long-term program with few definable guidelines. The convergence on pleiotropic hormones in life history considerations on the one hand, and developmental regulation on the other, however, should continue to drive investigations into endocrine system functions in this context.

Note added in proof

In December 2003 a first draft version of the honeybee genome was released by the Human Genome Sequencing Center at Baylor College of Medicine (http://www.hgsc.bcm.tmc.edu/projects/honeybee/). This genomic sequence information provides an unprecedented resource for functional genomic studies and it is predicted that it will be useful not only for research on the honey bee but also work on other social Hymenoptera. A similarly rich resource, not for sequence information but for concepts, is the recently published book by M.J. West-Eberhard (2003) which leaves no doubt about the importance of alternative phenotypes and their development regulation in evolutionary processes.

3.14 Biochemistry and Molecular Biology of Pheromone Production

G J Blomquist, University of Nevada, Reno, NV, USA
R Jurenka, Iowa State University, Ames, IA, USA
C Schal, North Carolina State University, Raleigh, NC, USA
C Tittiger, University of Nevada, Reno, NV, USA

3.14.1. Introduction and Overview

The elucidation of the structure of the first insect sex pheromone, bombykol ((*E,Z*)-10,12-hexadecadien-1-ol) (Butenandt *et al*., 1959) (**Figure 1**), from the silkworm moth, *Bombyx mori*, spanned more than 20 years and required a half million female abdomens. A few years later, (*Z*)-7-dodecenyl acetate (**Figure 1**) was identified as the sex pheromone of the cabbage looper, *Trichoplusia ni* (Berger, 1966). At about the same time Silverstein *et al*. (1966) identified three terpenoid alcohols, ipsenol, ipsdienol, and verbenol (**Figure 1**), as the pheromone of the bark beetle, *Ips paraconfusus*. This latter finding led to the recognition that most insect pheromones consisted of multicomponent blends. This has since been shown to be true for most insects, while single-component pheromones are rare. Rapid improvements in analytical instrumentation and techniques reduced the number of insects needed for pheromone extracts from a half million or more to where now individual insects can sometimes provide sufficient material for chemical analysis. Over the last four decades, extensive research on insect pheromones has resulted in the chemical and/or behavioral elucidation of pheromone components from well over 3000 insect species, with much of the work concentrating on sex pheromones from economically important pests.

An early issue addressed in pheromone production was the origin of pheromone components. Ultimately, all precursors for pheromone biosynthesis can be traced through dietary intake. A question asked in several systems was whether pheromone components were derived from dietary components that were altered only minimally, or whether they were synthesized *de novo*. This simple question proved surprisingly difficult to answer, and different answers were obtained for different groups of insects. It is now clear that most insect pheromone components are synthesized by insect tissue, with a

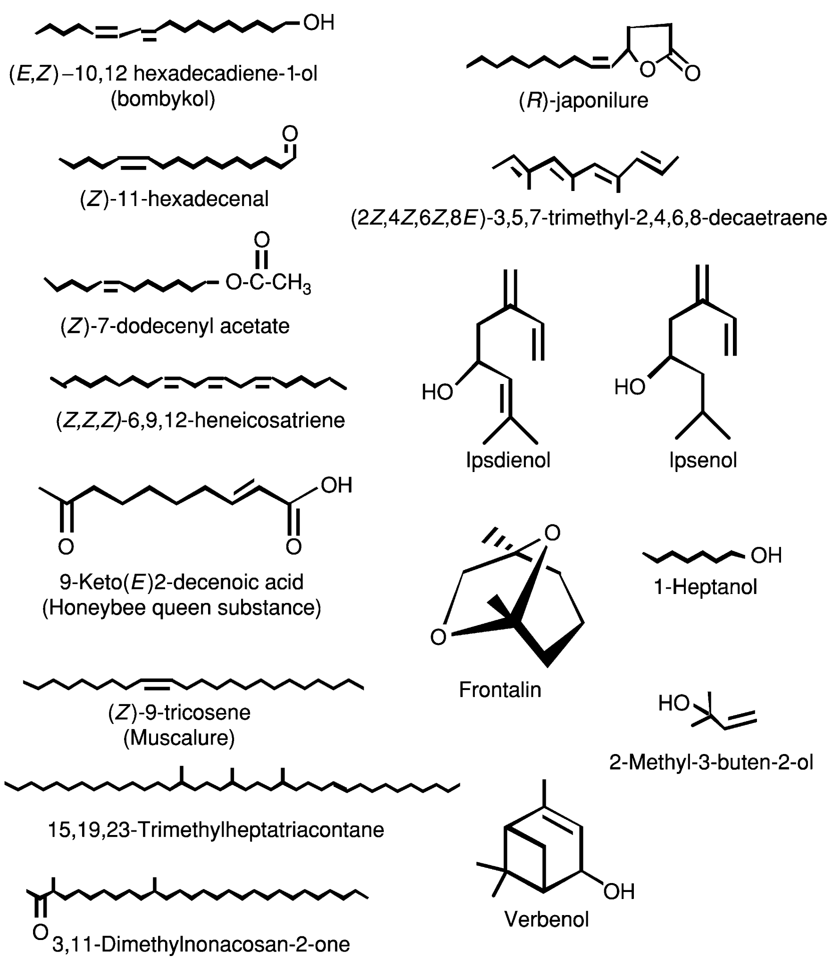

Figure 1 Selected pheromone components representing fatty acid, hydrocarbon, and isoprenoid-derived components. Components were selected based on historical interest and work performed on their biosynthesis.

number of notable exceptions (reviews: Tillman *et al.*, 1999; Eisner and Meinwald, 2003).

By the mid-1980s, it had became apparent that the products of normal metabolism, particularly those of the fatty acid and isoprenoid pathways, were modified by a few pheromone-tissue specific enzymes to produce the myriad of pheromone molecules. The elegant work of the Roelofs laboratory (review: Bjostad *et al.*, 1987) demonstrated that many of the lepidopteran pheromones could be formed by the appropriate interplay of highly selective chain shortening and unique Δ11 and other desaturases, followed by modification of the carboxyl carbon. This work has been extended, and there now exists a clear understanding of the biosynthetic pathways for many of the lepidopteran pheromones (review: Jurenka, 2003). The honeybee also uses highly specific chain shortening of fatty acids to produce the major component of the queen pheromone (Plettner *et al.*, 1996, 1998). In some insects, fatty acid elongation followed by decarboxylation produces the hydrocarbon and hydrocarbon-derived pheromones (review: Tillman *et al.*, 1999). Recent work in bark beetles has shown that *Ips* and *Dendroctonus* spp. produce their monoterpenoid-derived pheromones ipsenol, ipsdienol, and frontalin by modification of isoprenoid pathway products (review: Seybold and Tittiger, 2003).

The work on the biosynthesis and endocrine regulation of pheromone production has emphasized sex and aggregation pheromones in lepidopteran, coleopteran, dipteran, and blattodean models. Research on representative species from these orders was motivated by their economic importance, the relatively large amount of pheromone produced by some members, and extension of ongoing studies on hydrocarbon and fatty acid biosynthesis in some species.

The production and/or release of sex pheromones are influenced by a variety of environmental factors (Shorey, 1974). In general, insects do not release

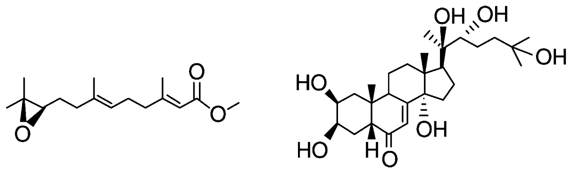

Figure 2 Structures of juvenile hormone (JH) III and 20-hydroxyecdysone (20E). The other major hormone that regulates pheromone production, PBAN, is shown in **Figure 10**.

pheromones until they are reproductively competent, although exceptions occur. Pheromone production is usually age related and coincides with the maturation of ovaries or testes, and in some cases with feeding. The observation that females of certain species have repeated reproductive cycles and that mating occurs only during defined periods of each cycle led to the proposal that pheromone production might be under hormonal control (Barth, 1965). Early work on cockroaches established that females require the presence of functional corpora allata (CA) in order to produce sex pheromone. It is now recognized that juvenile hormone (JH) (**Figure 2**) regulates pheromone production in a number of species, especially among beetles (review: Seybold and Vanderwel, 2003) and cockroaches (review: Schal *et al.*, 2003).

A unifying theme of this work on cockroaches and beetles was that the same hormone that regulated ovarian maturation (JH) also regulated pheromone production, coordinating sexual maturity with mating. Thus, in retrospect, it was not surprising that ovarian-produced 20-hydroxyecdysone (20E) (**Figure 2**), which plays an important role in reproduction in female Diptera, is also the key hormone inducing sex pheromone production in the female housefly, *Musca domestica* (review: Blomquist, 2003) and *Drosophila* (Wicker and Jallon, 1995a, 1995b).

It was recognized by the mid-1980s that female moths regulated pheromone production through a different mechanism than flies, cockroaches, and beetles (Raina and Klun, 1984), but it was not until 1989 that the structure of the pheromone biosynthesis activating neuropeptide (PBAN) was elucidated (Raina *et al.*, 1989; Raina, 1993) and work is ongoing deciphering its mode of action (review: Rafaeli and Jurenka, 2003). In some species, there does not appear to be a hormone regulating pheromone production.

3.14.2. Pheromone Chemistry

The pheromones of over 3000 insect species are now known. The website Pherolist is an up-to-date compilation of lepidopteran pheromones and lists over 500 compounds identified from over 1700 lepidopteran species. These numbers are a huge increase from the 80 pheromone components from about 120 lepidopterous species known in 1985 (Tamaki, 1985) and illustrate both the rapid growth in pheromone chemistry and the increased ease with which pheromones are identified. The book *Pheromones of Non-Lepidopteran Insects Associated with Agricultural Plants* (Hardie and Minks, 1999) discusses the pheromones of a number of pest species other than lepidopterans along with pheromones of beneficial insects. The *Handbook of Insect Pheromones and Sex Attractants* (Mayer and McLaughlin, 1991) contains a complete list of the pheromones identified from insects up to 1991.

The majority of lepidopteran pheromone components arise from fatty acids, and have carbon numbers from 7 to 29, with 12, 14, and 16 carbon components predominating. Of the 540 compounds included on the Pherolist website in 2003, 377 (70%) have an even number of carbons and 185 (34%) are acetate esters. The chemical classes alcohols, aldehydes, hydrocarbons, and epoxides each have between 65 and 85 components represented. Many of the lepidopteran pheromones have one or more double bonds with specific blends of (*Z*) and (*E*) isomers.

Many of the dipteran pheromones are hydrocarbons of 21 carbons and longer, and function as short range or contact pheromones. The pheromone of the housefly consists of (*Z*)-9-tricosene (**Figure 1**) (Carlson *et al.*, 1971), an epoxide and ketone derived from this hydrocarbon, and methyl-branched alkanes (review: Blomquist, 2003). Among the longest chain pheromones are the contact pheromones from the tsetse flies, which are often multimethyl branched hydrocarbons with up to 40 carbons (**Figure 1**) (Carlson *et al.*, 1978, 1984, 1998; Carlson and Schlein, 1991). The role of hydrocarbons in chemical communication in insects has become increasingly recognized over the past two decades (Howard, 1993).

A number of coleopteran pheromones are isoprenoid in origin (Francke *et al.*, 1995). The shortest chain pheromone described is 2-methyl-3-buten-2-ol from *Ips typographus* (Lanne *et al.*, 1989). Many of the components either contain multiples of 5 carbons or are derived from such precursors. **Figure 1** shows a number of pheromone components that are of isoprenoid origin, and include ipsdienol, ipsenol, and frontalin. Frontalin contains 8 carbons but is clearly isoprenoid in origin (Barkawi *et al.*, 2003). In addition to isoprenoids, the pheromones from coleopterans also consist of components derived from fatty acids and components of unknown orgin.

Many of the 4000+ described species of cockroaches use long-range volatile pheromones in mate-finding and cuticular contact pheromones in the final recognition process (Gemeno and Schal, 2004). Short-range volatile pheromones emitted by the male, coupled with nuptial tergal secretions, facilitate proper alignment of the pair prior to copulation (Nojima *et al.*, 1999). Pheromones also mediate intrasexual conflicts, especially when males establish dominance hierarchies and territories (Moore and Moore, 1999), and other behaviors. However, to date, few chemical structures have been elucidated, and the biosynthetic pathway of only one pheromone, the contact pheromone of the German cockroach, *Blattella germanica* has been described (major component is 3,11-dimethylnonacosan-2-one) (**Figure 1**) (Nishida *et al.*, 1974; Nishida and Fukami, 1983). Of particular note are the volatile sex pheromones of species in the genera *Periplaneta* and *Blatta* (periplanones) and 5-(2*R*,4*R*-dimethylheptyl)-3-methyl-2*H*-pyran-2-one (supellapyrone), the single-component sex pheromone of the brown-banded cockroach, *Supella longipalpa* (Charlton *et al.*, 1993; Leal *et al.*, 1995). Nevertheless, several cockroach pheromones have been investigated using behavioral and electrophysiological assays of crude body extracts. Interestingly, the pheromones of cockroach species that have served in important early studies on pheromone regulation (e.g., *Byrsotria fumigata*, *Blaberus* spp.) (see Barth, 1965; Barth and Lester, 1973) have yet to be identified.

3.14.3. Site of Pheromone Biosynthesis

There is much variability among insects in the anatomical location of pheromone production, just as there are many differences in the gross morphology and function of pheromone producing tissue. Complexity varies from simple unicellular glands distributed throughout the integument to elaborate internal cellular aggregates connected to a reservoir. Of the orders emphasized in this chapter (Lepidoptera, Coleoptera, Blattodea, and Diptera), the most common location for pheromone production is the abdomen. There are a number of excellent reviews of the ultrastructure of exocrine cells in general (Percy-Cunningham and MacDonald, 1987; Quennedey, 1998; Ma and Ramaswamy, 2003) and social insects in particular (Billen and Morgan, 1998). Definitive proof that pheromone production and release occur in certain tissues comes from studies where the isolated tissue has been shown to incorporate labeled precursors into pheromone components.

3.14.3.1. Location of Pheromone Production in Lepidoptera

The oxygenated lepidopteran pheromone components are usually produced and released from extrudable glands located between the 8th and 9th abdominal segments (Percy-Cunningham and MacDonald, 1987; Ma and Ramaswamy, 2003). The secretory cells in these glands typically contain a well-developed endoplasmic reticulum that is involved in fatty acid metabolism. Extensive studies examining the pheromone products and precursors from these glands in a number of species show that unusual specific fatty acids that had the same carbon number, double bond positions, and stereochemistry as the acetate, alcohol, or acetate ester pheromone components were present. The role of these glands in pheromone production has been clearly demonstrated with radiochemical studies (Bjostad *et al.*, 1987; Jurenka, 2003). Although a large number of moths utilize a gland located between the 8th and 9th segments, exceptions occur. It was shown in *Theresimima ampelophaga* (Zygaenidae) that the gland is located on the dorsal part of the 3–5th abdominal segments (Hallberg and Subchev, 1997).

In contrast, the site of synthesis of the hydrocarbon and hydrocarbon-derived pheromone components is more complicated. 2-Methylheptadecane is not synthesized in the pheromone gland of *Holomelina aurantiaca*, but rather is synthesized by epidermal tissue, transported by lipophorin, and then sequestered into and released from the pheromone gland (Schal *et al.*, 1998a). A similar situation exists for the gypsy moth, *Lymantra dispar*, in which the hydrocarbon precursor is synthesized in epidermal tissue, then transported by lipophorin to the pheromone gland where it is epoxidized and released (see Section 3.14.4.3.6) (Jurenka *et al.*, 2003).

3.14.3.2. Site of Pheromone Biosynthesis in Coleoptera

In many coleopteran species, pheromone production localizes to the abdomen, e.g., among the Scarabaeidae (Tada and Leal, 1997), Anobiidae (Levinson *et al.*, 1983), Dermestidae (Barak and Burkholder, 1977), and others (review: Plarre and Vanderwel, 1999; Tillman *et al.*, 1999). In some cases there are defined glands, whereas in others, groups of cells in defined anatomical locations may not form a gland, but are nevertheless a localized site of pheromone biosynthesis. Other anatomical locations for pheromone production have also been identified for some species. These include putative pheromone glands on the antennae of *Batrisodes oculatus* (de Mazo

and Vit, 1983) and on the forelimbs of *Tribolium castaneum* (Faustini *et al*., 1982).

Pheromone biosynthetic cells of many beetles are generally dermally derived, with one notable exception. Monoterpenoid pheromone components have been reported to be synthesized in the fat body of male boll weevils, *Anthonomus grandis* (Wiygul *et al*., 1990). The fat body is an unexpected location for boll weevil pheromone biosynthesis, because it requires transport of pheromone components into the lumen of the alimentary canal for release. This is unusual, because other pheromone glands and cells tend to be physically linked to release sites either by proximity or by specialized structures such as ducts or ductules (review: Ma and Ramaswamy, 2003). Recent work (Nural, Tittiger, Fu and Blomquist, unpublished data) demonstrate that isolated gut tissue from male *A. grandis* incorporated labeled acetate into components that coeluted on high-performance liquid chromatography (HPLC) with the four C_{10} pheromone components. It is difficult to obtain *A. grandis* gut tract tissue free from adhering fat body, making it impossible to conclude with certainity that fat body tissue is not involved. The clear demonstration that several bark beetles synthesize their frass-associated isoprenoid pheromone components in midgut tissue (see below) along with the data from *A. grandis* suggests that frass-associated pheromones in general may be produced in gut tissue.

The site of *de novo* monoterpenoid pheromone biosynthesis in bark beetles (especially *Ips* and *Dendroctonus* spp.) has been clearly demonstrated. Early work localized the pheromone and its release to the hindgut (Bordon *et al*., 1969; Byers, 1983), but did not determine the site of synthesis. Pheromone component precursors were localized in the abdomen–thorax border (Ivarsson *et al*., 1998), and the anterior midgut was determined as the site of *de novo* synthesis through the use of molecular probes to 3-hydroxy-3-methylglutaryl-CoA (HMG-R) reductase and radiotracer studies (**Figure 3**) (Hall *et al*., 2002a, 2002b). Electron microscopy studies show that pheromone-biosynthetic midgut cells have crystalline arrays of smooth endoplasmic reticulum, while nonpheromone-producing cells do not (Nardi *et al*., 2002). These studies also confirmed that bark beetle pheromones are synthesized by insect tissues, and not by microorganisms, as had been suggested by earlier studies (Brand *et al*., 1975, 1976). Pheromone components are secreted into the gut lumen through an apocrine mechanism, and all anterior midgut cells appear to be involved. Pheromone-biosynthetic cells are typically dedicated to that function, but anterior midgut cells of bark beetles apparently fulfill the dual roles of pheromone production and food digestion (Nardi *et al*., 2002).

Why midgut tissue? In considering the evolution of pheromone components, it is generally thought that pheromone molecules, as other signaling chemicals, originally had another purpose and were co-opted for signal function. Components were then shaped by selective forces acting on preexisting structures, and pheromones evolved so that the signal would be stronger and more easily discriminated. For bark beetles, it is thought that monoterpene components arose from the detoxification of oleoresin tree defensive components, and that many of the detoxification reactions involved hydroxylation reactions (Wood, 1982; Vanderwel and Oehlschlager, 1987). To lessen dependence upon host chemicals and increase host range, bark beetles then apparently evolved the ability to synthesize their monoterpenoid pheromones *de novo*, and with this, evolved the JH III regulation of pheromone production. As the ancient beetles chewed through the bark and phloem, they encountered tree terpenoids. Gut tissue was the first line of defense, and detoxification enzymes (cytochrome P450 hydoxylases) could have evolved to detoxify monoterpenes in this tissue. As *de novo* synthesis evolved, it is possible that production of pheromone arose in midgut tissue so that the hydroxylation reactions that were already present could be used.

3.14.3.3. Site of Pheromone Production in Diptera

The hydrocarbon pheromone components of many Diptera evolved from, and still function as, cuticular lipids. Thus, it is expected that these pheromone components are synthesized in the same specialized epidermal cells (oenocytes) that produce cuticular hydrocarbons. After synthesis, pheromone components are secreted into the hemolymph, where they are transported by lipophorin, as has been demonstrated in *Drosophila* (Ferveur *et al*., 1997) and the housefly (Schal *et al*., 2001), before being deposited on the cuticular surface. During the process of grooming, relatively large amounts of (*Z*)-9-tricosene accumulate on the legs of female houseflies (Dillwith and Blomquist, 1982). The mechanism of how hydrocarbon pheromones, and hydrocarbons in general, are unloaded from lipophorin and transported across the cuticle is not known.

3.14.3.4. Site of Pheromone Production in Blattodea

As in Coleoptera, early reports considered various organs in the head, thorax, and abdomen as possible sites of pheromone production in cockroaches, but

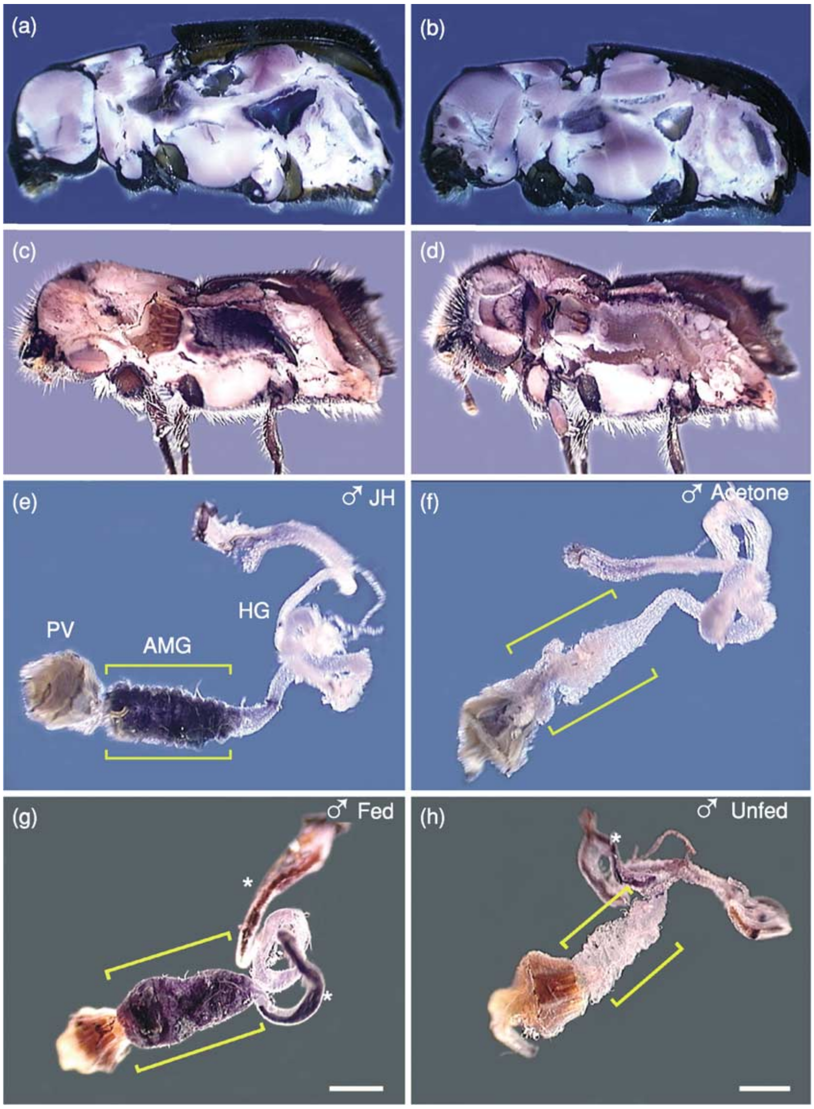

Figure 3 Tissue localization of *HMG-R* expression. Exposed whole mounts show that HMG-R mRNA is observed in the midgut of JH III-treated male *Dendroctonus jeffreyi* (a) and *Ips pini* (c), but not in untreated insects (b, d). Panels (e) through (h) show whole mount hybridizations of isolated *I. pini* alimentary canals. *HMG-R* expression in the anterior midgut (AMG, marked by yellow brackets) correlates with pheromone production in starved, JH III-treated males (e) and fed males (g), while starved and untreated males (f, g), which do not produce monoterpenoid pheromone components, do not strongly express *HMG-R*. Asterisks mark nonspecific signal in the hindguts. PV, proventriculus; HG, hindgut. Scale bar = 0.5 mm. (Modified from Hall *et al.*, 2002a, 2002b.)

most of the more recent research implicates specialized abdominal glands. Periplanone-A and periplanone-B, the sex pheromone components of the American cockroach, *Periplaneta americana*, appear to be concentrated in the midgut and released in feces. However, female calling involves opening the genital vestibulum (i.e., atrial gland), without excretion of feces, and this glandular tissue contains most of the periplanone-B, up to 60 ng (Abed *et al.*, 1993a). The epithelium of the atrial gland consists of class-1 glandular cells, in which the secretion passes directly to the cuticle and not through a duct. However, Yang *et al.* (1998) concluded that both periplanone-A and periplanone-B were most abundant in the colon and that this tissue produced the strongest electroantennogram (EAG) responses. To date, no definitive proof of the sites of pheromone biosynthesis is available through isotopic tracing of pheromone precursors in isolated tissues.

The volatile sex pheromones of other cockroaches have been localized to abdominal tergites and sternites. Females of the German cockroach, *B. germanica*, produce the pheromone in the 10th abdominal

tergite (pygidium) (Liang and Schal, 1993; Tokro *et al.*, 1993), *S. longipalpa* in the 4th and 5th tergites (Schal *et al.*, 1992), and *Parcoblatta lata* (wood cockroach) females produce the pheromone in tergites 1–7 (Gemeno *et al.*, 2003). In all three species, the tergal glands are composed of multiple class-3 secretory units, each leading through a long unbranched duct to a single cuticular pore. The secretory cells are characterized by abundant mitochondria, smooth endoplasmic reticulum (SER), rough endoplasmic reticulum (RER), a large nucleus, and numerous secretory vesicles that discharge through an end-apparatus with numerous long microvilli into the duct and to the cuticular surface. In all three species pheromone is released during a calling behavior.

Male cockroaches also release volatile sex pheromones from tergal or sternal glands. In *Nauphoeta cinerea* (lobster cockroach) glands on sternites 3–7 are exposed during calling, releasing a volatile male pheromone consisting of 3-hydroxy-2-butanone, 2-methylthiazolidine, 4-ethyl-2-methoxyphenol, and 2-methyl-2-thiazoline (Sreng, 1990; Sirugue *et al.*, 1992). In some species the male tergal glands form specialized regions on the cuticular surface and they produce a blend of close-range attractants, phagostimulants, and nutrients that the male deploys to place the female in a precopulatory position. For example, the tergal glands of *B. germanica* consist of transverse cuticular depressions on the 7th and 8th tergites, connected to numerous class-3 secretory cells (Sreng and Quennedey, 1976; Brossut and Roth, 1977).

Cuticular contact pheromones mediate species and sex recognition and, in most cases, they function as courtship-inducing pheromones. They are thought to be distributed throughout the epicuticular surface. The blend of hydrocarbon-derived ketones of *B. germanica* females is produced by oenocytes, which are localized within the abdominal integument, separated from the hemocoel by a basal lamina (Liang and Schal, 1993). Fan *et al.* (2003) enzymatically dissociated the integument underlying the sternites into a cell suspension. After further Percoll gradient centrifugation, each fraction was assayed for incorporation of $[^{14}C_1]$propionate into methyl-branched hydrocarbons. Only oenocytes produced hydrocarbons and methyl ketone pheromones, whereas the much larger population of epidermal cells did not (Fan *et al.*, 2003; Fan, unpublished data). As in the dipterans *M. domestica* and *Drosophila* and the moth *Holomelina*, the hydrocarbon-derived pheromones of *B. germanica* are produced by oenocytes and transported by lipophorin (see Section 3.14.5.4).

3.14.4. Biochemistry of Pheromone Production

3.14.4.1. Modification of "Normal Metabolism"

By the mid-1980s (Prestwich and Blomquist, 1987), the biosynthetic pathways of pheromones for a limited number of species had been determined, and work was progressing toward the characterization of some of the unique enzymes involved. It became apparent that the products and intermediates of normal metabolism, particularly those of the fatty acid and isoprenoid pathways, were modified by a few specific enzymes in pheromone gland tissue to produce the myriad of pheromone molecules. Many of the lepidopteran pheromones could be formed by the appropriate interplay of highly selective chain shortening and a unique Δ11 and other desaturases followed by modification of the carboxyl carbon (Bjostad *et al.*, 1987). This work has been extended, and a clear understanding of the biosynthetic pathways for many of the lepidopteran pheromones is now known (Jurenka, 2003). The Δ11 and other pheromone-specific desaturases in Lepidoptera have been characterized at the molecular level (Knipple and Roelofs, 2003). Chain shortening of fatty acids is also involved in producing the queen pheromone in honeybees (Plettner *et al.*, 1996, 1998). In some insects, fatty acid elongation followed by decarboxylation produces the hydrocarbon pheromones, and this process includes examples of lepidopterans (Jurenka, 2003), dipterans (Blomquist, 2003; Jallon and Wicker-Thomas, 2003), the German cockroach (Schal *et al.*, 2003), and the social insects (Blomquist and Howard, 2003). More recent work in bark beetles has shown that *Ips* and *Dendroctonus* spp. produce their monoterpenoid-derived pheromones ipsenol, ipsdienol, and frontalin by modifications of isoprenoid pathway products (Seybold and Vanderwel, 2003). Until that work, it was considered very rare for animals to produce monoterpenoids (C_{10} isoprenoids).

3.14.4.2. Pheromone Biosynthesis in Moths

Bjostad and Roelofs (1983) were the first to determine correctly how the major pheromone component for a particular moth was biosynthesized. They utilized the moth *T. ni* because the female produces a relatively large amount of pheromone (about 1 μg). They began by demonstrating that pheromone glands utilize acetate to produce the common fatty acids octadecanoate and hexadecanoate, which undergo Δ11 desaturation to produce *Z*11–18:acid and *Z*11–16:acid. However, the main pheromone component is *Z*7–12:OAc, which presumably is

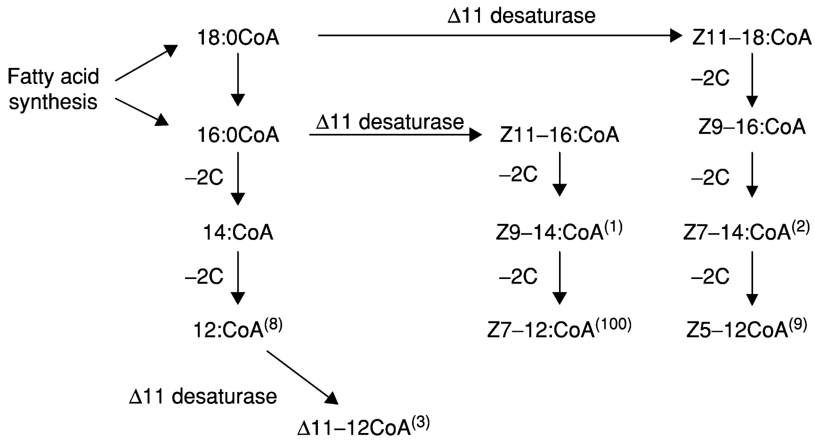

Figure 4 Biosynthetic pathways for producing the intermediate CoA derivatives of the pheromone blend of the cabbage looper, *Trichoplusia ni*. The CoA derivatives followed by the superscript number in parenthesis are reduced to an alcohol and acetylated to form the acetate esters that make up the pheromone blend. The superscript numbers indicate the approximate ratio of components found in the pheromone gland (Bjostad *et al.*, 1984). (Reprinted with permission from Jurenka, R.A., **2003**. Biochemistry of female moth sex pheromones. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Elsevier, San Diego, CA, pp. 53–80; © Elsevier.)

made from *Z*7–12:acid. To demonstrate how the fatty acid precursor *Z*7–12:acid was produced, [$^3H_{16}$]*Z*11–16:acid was applied to glands and found to be incorporated into both *Z*7–12:acid and *Z*7–12:OAc. They concluded that limited chain-shortening of *Z*11–16:acid could account for this incorporation. The other minor components are produced in a similar way (**Figure 4**). Thus the pheromone components are produced through a fatty acid biosynthesis pathway involving a Δ11 desaturase and limited chain-shortening enzymes. The appropriate chain length fatty acid is then reduced and acetylated to form the acetate ester. Subsequent research has demonstrated that similar pathways occur in a wide variety of female moths (Bjostad and Roelofs, 1984; Roelofs and Wolf, 1988).

Most female moths produce their pheromone through modifications of fatty acid synthesis pathways and thus techniques in fatty acid research were utilized to determine biosynthetic pathways (Bjostad *et al.*, 1987; Morse and Meighen, 1987b). The main techniques include thin-layer chromatography, gas chromatography (GC), and GC-mass spectrometry (MS) with the latter being the primary method utilized. The advantage of using GC–MS is that the label (stable isotopes of deuterium or carbon-13) can be explicitly shown to be present in the compound of interest. By monitoring for diagnostic ions that correspond to unlabeled and labeled products, it can be determined with considerable certainty that the label is associated with a particular compound. By utilizing different proposed intermediate labeled fatty acids a biosynthetic pathway can be deduced. For example, a recent study determined that *Z*11–16:Ald occurs by Δ11-desaturation of 16:CoA followed by reduction in the moths *Helicoverpa zea* and *H. assulta* (Choi *et al.*, 2002). However, *Z*9–16:Ald, the major pheromone component in *H. assulta*, was produced by a Δ9-desaturase using 16:CoA as a substrate, but in *H. zea* *Z*9–16:Ald was produced by Δ11-desaturation of 18:CoA to produce *Z*11–18:CoA that is then chain-shortened to *Z*9–16:CoA (Choi *et al.*, 2002). These types of studies have shown that the key enzymes of sex pheromone biosynthetic pathways are fatty acid biosynthesis, desaturases, chain-shortening enzymes, and specific enzymes to produce a functional group.

3.14.4.3. Enzymes Involved in Lepidopteran Pheromone Production

3.14.4.3.1. Fatty acid synthesis A combination of acetyl-CoA carboxylase and fatty acid synthase produce saturated fatty acids. Although no direct enzymatic studies have been conducted using pheromone gland cells, these enzymes are presumably similar to enzymes found in other cell types. Labeling studies conducted with acetate indicated that pheromone glands produce 16:acid and 18:acid saturated products (Bjostad and Roelofs, 1984; Tang *et al.*, 1989; Jurenka *et al.*, 1991b, 1994).

3.14.4.3.2. Chain-shortening enzymes Insects in general have the ability to shorten long-chain fatty acids to specific shorter chain lengths (Stanley-Samuelson *et al.*, 1988). This chain-shortening pathway has not been characterized at the enzymatic level in insects. It presumably is similar to the characterized pathway as it occurs in vertebrates which

is essentially a partial β-oxidation pathway located in peroxisomes (Hashimoto, 1996). The evidence for limited chain-shortening enzymes in pheromone glands was originally demonstrated by Bjostad and Roelofs (1983) using the cabbage looper moth, *T. ni* in which it was shown that *Z*11–16:acid labeled the intermediate fatty acid *Z*7–12:OAc. A similar study using *Argyrotaenia velutinana* demonstrated that deuterium-labeled 16:acid was chain-shortened to 14:acid, which was used to make *Z* and *E*11–14:acid (Bjostad and Roelofs, 1984). Since then considerable evidence in a number of moths has accumulated to indicate that limited chain shortening occurs in a variety of pheromone biosynthetic pathways.

Radio and stable isotopes were topically applied directly to an intact pheromone gland to provide evidence for chain shortening. The position of the label was on the terminal methyl carbon making it difficult for any type of rearrangement to occur (Wolf and Roelofs, 1983; Rosell *et al.*, 1992). A more direct *in vitro* enzyme assay was utilized to demonstrate substrate preferences in a study using cabbage looper moths (Jurenka *et al.*, 1994). This study was prompted by the finding of a mutant line of cabbage loopers that produced a greatly increased amount of *Z*9–14:OAc (Haynes and Hunt, 1990), which is a minor component of normal cabbage loopers. Increased amounts of *Z*9–14:OAc indicate that chain shortening was affected in the mutant cabbage loopers. To determine if chain shortening was affected, substrate specificities for both normal and mutant cabbage loopers were determined using an *in vitro* enzyme assay (Jurenka *et al.*, 1994). Pheromone glands from normal cabbage loopers preferred to chain shorten *Z*11–16:CoA to *Z*7–12:CoA with two rounds of chain shortening, whereas pheromone glands from the mutant cabbage looper apparently have the ability to chain shorten by only one round. Therefore, *Z*11–16:CoA was chain shortened to *Z*9–14:CoA.

Changes in chain-shortening reactions have also been implicated in the alteration of pheromone ratios in several other species. In a laboratory selection pressure experiment using *A. velutinana*, the *Z*/*E* ratio of 11–14:OAc could not be changed much from a 92/8 ratio (Roelofs *et al.*, 1986). However, it was found that the ratio of *E*9–12:OAc/*E*11–14:OAc could be selected (Sreng *et al.*, 1989) and by comparing ratios of the 14-carbon/12-carbon pheromone components and *Z*/*E* isomers of each chain length it was determined that chain-shortening enzymes were selective for the *E* isomer (Roelofs and Jurenka, 1996). Another example where a change in chain shortening can account for a new pheromone blend is the larch budmoth, *Zeiraphera diniana*. The pheromone was first identified as *E*11–14:OAc (Roelofs *et al.*, 1971), but it was later determined that some populations utilize *E*9–12:OAc, which is made by chain shortening of *E*11–14:acid (Guerin *et al.*, 1984; Baltensweiler and Priesner, 1988). Another case where changes in chain shortening may have produced two populations of insects was found in the turnip moth, *Agrotis segetum*. A Swedish population has a ratio of *Z*9–14:OAc/*Z*7–12:OAc/*Z*5–10:OAc of 29/59/12, whereas, a Zimbabwean population has a ratio of 2/20/78. After conducting labeling studies, it was determined that chain-shortening enzymes could be affected to produce the alteration in pheromone ratios (Wu *et al.*, 1998). These studies indicate that alteration in chain-shortening enzymes can have a major effect on pheromone blends.

3.14.4.3.3. Desaturases Desaturases introduce a double bond into the fatty acid chain. A variety of desaturases have been described that are involved in the biosynthesis of female moth sex pheromones. The desaturases identified so far include enzymes that act on saturated and monounsaturated substrates. These include Δ5 (Foster and Roelofs, 1996), Δ9 (Löfstedt and Bengtsson, 1988; Martinez *et al.*, 1990), Δ10 (Foster and Roelofs, 1988), Δ11 (Bjostad and Roelofs, 1981, 1983), and Δ14 (Zhao *et al.*, 1990) desaturases that utilize saturated substrates. The combination of these desaturases along with chain shortening can account for the majority of double bond positions in the various chain-length monounsaturated pheromones so far identified (Roelofs and Wolf, 1988). **Figure 5** illustrates the large number of monounsaturated compounds that can be generated through a combination of desaturation and chain shortening. Addition of various functional groups, acetate esters, alcohols, and aldehydes, increases the potential number of pheromone components. Notice that some of the intermediate compounds could be produced in two different ways. Therefore, although the desaturation and chain-shortening steps occur in a wide variety of moths, the order in which they occur and the type of desaturase must still be determined experimentally.

Some pheromone components are dienes and these can be produced by either the action of two desaturases or one desaturase and isomerization around the double bond. Some dienes with a 6,9-double bond configuration are produced using linoleic acid. Desaturases that utilize monounsaturated acyl-CoA substrates include Δ5 (Ono *et al.*, 2002), Δ9 (Martinez *et al.*, 1990), Δ11 (Foster and Roelofs, 1990), Δ12 (Jurenka, 1997), and Δ13

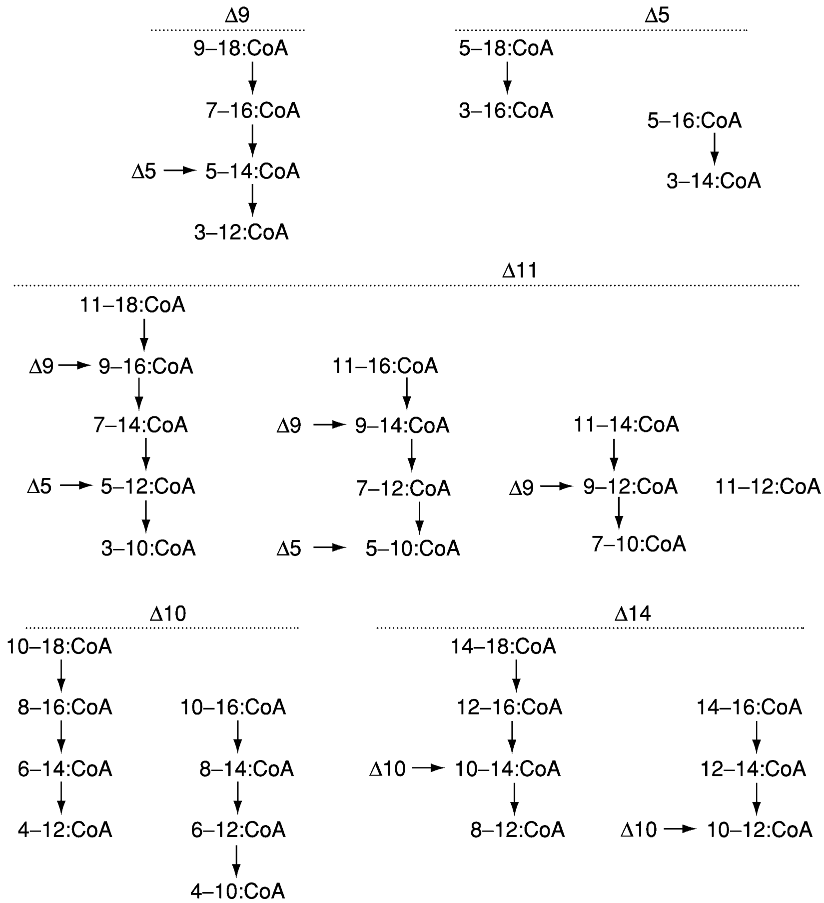

Figure 5 Combination of desaturation and chain shortening can produce a variety of monounsaturated acyl-CoA precursors that can be modified to form acetate esters, aldehydes, and alcohols. The number followed by the Δ sign indicates a desaturase that introduces a double bond into the first indicated chain length acyl-CoA. The arrow pointing down indicates limited chain-shortening by two carbons. The arrow pointing to the right indicates that desaturation could produce the compound found within a chain-shortening pathway. This indicates that certain compounds could be produced in two different ways. Modification of all 16-, 14-, 12-, and 10-carbon acyl-CoA derivatives on the carbonyl carbon can account for the majority of monounsaturated acetate esters, aldehydes, and alcohols identified as sex pheromones. (Reprinted with permission from Jurenka, R.A., **2003**. Biochemistry of female moth sex pheromones. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Elsevier, San Diego, CA, pp. 53–80; © Elsevier.)

(Arsequell *et al*., 1990). These can act sequentially to produce the diene (Foster and Roelofs, 1990; Jurenka, 1997) or conjugated dienes could be produced by the action of one desaturase followed by isomerization (Ando *et al*., 1988; Löfstedt and Bengtsson, 1988; Fang *et al*., 1995a).

The biosynthesis of triene pheromone components has not been extensively investigated. Pheromones with a triene double bond system, that is *n*-3 (3,6,9-), are probably produced from linolenic acid (Millar, 2000). This was demonstrated in the saltmarsh caterpillar, *Estigmene acrea*, and the ruby tiger moth, *Phragmatobia fuliginosa* (Rule and Roelofs, 1989). Moths in the families Geometridae, Arctiidae, and Noctuidae apparently utilize linoleic and linolenic acid as precursors for their pheromones. Most of these pheromones are produced by chain elongation and decarboxylation to form hydrocarbons. Oxygen is added across one of the double bonds in the polyunsaturated hydrocarbon to produce an epoxide (Millar, 2000).

3.14.4.3.3.1. Molecular biology of the desaturases More recent research has identified a variety of desaturases at the gene level with the first gene encoding a Δ11 desaturase being identified in the cabbage looper, *T. ni* (Knipple *et al*., 1998). Since then a number of desaturase genes have been cloned and functionally expressed (Knipple and Roelofs, 2003). Expression in a strain of yeast lacking an endogenous desaturase was utilized to demonstrate functionality. This strain of yeast will not grow in a media lacking added unsaturated fatty acids but will grow if a functional desaturase is

inserted into the yeast genome. After growth, the fatty acids are analyzed to determine double bond positions and thus the desaturase can be characterized regarding double bond insertion and chain-length specificity.

Desaturase encoding cDNAs from pheromone glands that produce *Z*9, *Z*10, *Z*11, and *E*11 double bonds in 14- and 16-carbon acids have been identified so far. The *Z*9-desaturase is comparable to the metabolic desaturase found in the fat body. A *Z*10-desaturase was characterized from *Planotortrix octo* that produces Z10–16:acid (Hao *et al*., 2002), which would be chain shortened to produce the precursor to the pheromone *Z*8–14:OAc (Foster and Roelofs, 1988). Several Δ11-desaturases have been characterized including the ones from *T. ni* (Knipple *et al*., 1998) and *H. zea* (Rosenfield *et al*., 2001) that produce primarily *Z*11–16:acid. A single Δ11-desaturase was characterized from *A. velutinana* that produces both *Z*11– and *E*11–14:acid (Liu *et al*., 2002a). This desaturase is unique in that it produces both isomers and uses 14:acid as a substrate. Another unique Δ11-desaturase was identified from *Epiphyas postvittana* that not only produced *E*11–14:acid and *E*11–16:acid from saturated precursors, but also *E*9,*E*11–14:acid from a *E*9–14:acid precursor (produced by chain shortening *E*11–16:acid) (Liu *et al*., 2002b). Identification of desaturases in *Ostrinia nubilalis* and *O. furnicalis* produced the surprise finding that Δ11- and Δ14-desaturases are found in both moths (Roelofs *et al*., 2002). The Δ11-desaturase produced both *Z*11– and *E*11–14:acid and the Δ14-desaturase produced both *Z*14– and *E*14–16:acids. This finding has implications regarding the evolution of pheromone blends in moths (Baker, 2002).

3.14.4.3.4. Specific enzymes to produce functional group on carbonyl carbon Once a specific chain-length pheromone intermediate that has the appropriate double bonds is produced, the carbonyl carbon is modified to form a functional group. The majority of oxygenated pheromone components are acetate esters (or other esters), alcohols, and aldehydes. Production of these components requires the reduction of a fatty-acyl precursor to an alcohol which is a two-step reaction requiring a fatty acid reductase and an aldehyde reductase (Morse and Meighen, 1987b). Thus, alcohol formation goes through an aldehyde intermediate. Therefore, aldehydes could be produced by direct reduction of fatty acids. Another route for aldehyde formation is oxidation of alcohols. A cuticular oxidase has been characterized from pheromone glands of *H. zea* and *Manduca sexta* that produce aldehydes as pheromones (Teal and Tumlinson, 1988; Fang *et al*., 1995b). In those insects that utilize both an alcohol and an aldehyde as part of their pheromone, it is unclear how the production of both components occurs.

Production of acetate ester pheromone components utilizes an enzyme called acetyl-CoA:fatty alcohol acetyltransferase that converts a fatty alcohol to an acetate ester (Morse and Meighen, 1987a). Therefore, alcohols could be utilized as substrates for both aldehyde and acetate ester formation. Morse and Meighen (1987a) first demonstrated its presence in the spruce budworm, *Choristoneura fumiferana*, where it is involved in producing the acetate ester that serves as a precursor to the aldehyde pheromone (Morse and Meighen, 1987b). In some other tortricids, *A. velutinana*, *C. rosaceana*, and *Platynota idaeusalis,* an *in vitro* enzyme assay was utilized to demonstrate specificity of the acetyltransferase for the *Z* isomer of 11–14:OH (Jurenka and Roelofs, 1989). This specificity contributes to the final ratio of pheromone components. These results indicate that the family Tortricidae has members that have an acetyltransferase that is specific for the *Z* isomer of monounsaturated fatty alcohols. In contrast, several studies have shown no substrate preference for the acetyltransferase in other moths (Bestmann *et al*., 1987; Teal and Tumlinson, 1987; Jurenka and Roelofs, 1989). Therefore, this unique acetyltransferase apparently evolved within the Tortricidae.

3.14.4.3.5. Production of specific pheromone blends Most female moths utilize a blend of components produced in a specific ratio for pheromone attraction of conspecific males. A major question is how these species-specific ratios of components are produced. Research from several sources indicates that these ratios are produced by the inherent specificity of certain enzymes present in the biosynthetic pathways. The combination of these enzymes acting in concert produces the species-specific pheromone blend. Several examples will be utilized to illustrate this point.

The cabbage looper, *T. ni* uses *Z*7–12:OAc as the major sex pheromone component, which is produced by Δ11-desaturation of 16:CoA followed by two rounds of chain shortening, reduction, and acetylation. The Δ11-desaturase has been characterized (Wolf and Roelofs, 1986) and the gene isolated (Knipple *et al*., 1998). These studies indicate that 16:CoA and 18:CoA are substrates with 16:CoA as the preferred substrate and indeed *Z*11–16:acid is the most abundant monounsaturated fatty acid in pheromone glands (Bjostad *et al*., 1984). The next

step in the pathway is limited chain shortening and it was shown that *Z*11–16:CoA is the preferred substrate for these enzymes (Jurenka *et al*., 1994). After chain shortening the 14-carbon and 12-carbon intermediates are reduced to an alcohol and acetylated. The acetyltransferase enzyme is not specific and will accept a variety of substrates (Jurenka and Roelofs, 1989). From these observations, it can be inferred that the final ratio of pheromone components is produced by the specificity found within the Δ11-desaturase and chain-shortening enzymes.

A blend of seven acetate esters is used by *A. velutinana* that are produced in a biosynthetic pathway similar to the one just described, except that the Δ11-desaturase starts with 14:CoA as the substrate and produces both *Z* and *E* isomers of 11–14:CoA in about a 60/40 ratio (Wolf and Roelofs, 1987). Recent cloning of the Δ11-desaturase from redbanded leafroller (RBLR) females indicates that the expressed enzyme produces a ratio of *Z/E* of about 6/1 (Liu *et al*., 2002a). However, the final ratio of *Z*11– to *E*11–14:OAc is 92/8 (Miller and Roelofs, 1980). A selective increase in the *Z* isomer occurs within the biosynthetic pathway and it was determined that acetyl:CoA fatty alcohol acetyltransferase shows specificity for the *Z* isomer (Jurenka and Roelofs, 1989). Therefore, selective acetylation of *Z*11–14:OH and production of >60% *Z*11–14:CoA indicate that these enzymes have the inherent specificity to produce the 92/8 ratio of the major pheromone components *Z*11– and *E*11–14:OAc. Two minor pheromone components are produced by chain shortening *Z*11– and *E*11–14:OAc. The ratio of *Z*9– to *E*9–12:OAc is about 1 to 2. This indicates that the chain-shortening enzymes may prefer *E*11–14:CoA or that very little *Z*11–14:CoA is available to chain shorten. This combined information indicates that in *A. velutinana* pheromone glands, the final ratio of pheromone components can be produced through the concerted action of a Δ11-desaturase that produces at least a 60/40 ratio of *Z/E* intermediate isomers. The final ratio of acetate esters (92/8) is produced through the specificity for the *Z* isomer by the acetyltransferase. The minor components are produced by specificity in chain shortening.

Another insect that utilizes specific ratios of *Z*11– and *E*11–14:OAc is the European corn borer, *O. nubilalis*. Two strains are known in which one produces a ratio of *Z/E* of about 97/3 (*Z* strain) and the other produces an opposite ratio of *Z/E* of about 1/99 (*E* strain). Hybridization studies between the two strains indicated that offspring have an acetate ester ratio of *Z/E* of about 30/70 (Klun and Maini, 1982). The Δ11-desaturase from both strains produced a product with about 30/70 *Z/E* in an *in vitro* enzyme assay (Wolf and Roelofs, 1987). These results indicate that the final ratio of acetate ester isomers is produced after the desaturation step. The enzymes that follow the desaturase are a reductase to make an alcohol and an acetyltransferase to produce the acetate esters. Two studies have shown that the acetyltransferase is similar between the two strains (Jurenka and Roelofs, 1989; Zhu *et al*., 1996). However, labeled acids applied to glands *in vivo* were selectively incorporated into the correct pheromone ratio indicating that the reductase shows specificity (Zhu *et al*., 1996). Therefore, the final pheromone ratios produced by females of the European corn borer are made through the action of a Δ11-desaturase that can produce both *Z* and *E* isomers. The final acetate ester ratio is strain dependent and is produced through the specificity found in the reductase system.

The above three examples illustrate how a species-specific pheromone blend is produced by the concerted action of desaturases, chain-shortening enzymes, and a reductase and an acetyltransferase. The specificity inherent in certain enzymes in the pathway produces the final blend of pheromone components.

3.14.4.3.6. Hydrocarbon pheromones Moths in the families Geometridae, Arctiidae, Amatidae, Lymantriidae, Lyonetiidae, and some Noctuidae utilize hydrocarbons or epoxides of hydrocarbons as their sex pheromones. Biosynthesis of hydrocarbons occurs in oenocyte cells that are associated with either epidermal cells or fat body cells (Romer, 1991). Once the hydrocarbons are biosynthesized they are transported to the sex pheromone gland by lipophorin (Schal *et al*., 1998a). When the transport of hydrocarbon sex pheromones in arctiid moths was investigated in detail by Schal *et al.* (1998a), it was found that a very specific uptake was occurring at pheromone glands. Lipophorin was shown to contain both the sex pheromone and cuticular hydrocarbons; however, only the pheromone gland had the sex pheromone. Other studies have shown similar pathways in other moths (Jurenka and Subchev, 2000; Subchev and Jurenka, 2001; Wei *et al*., 2003).

Most moth sex pheromones that are straight chain hydrocarbons also usually have an odd number of carbons. Most of these are polyunsaturated with double bonds in the 3,6,9- or 6,9-positions, indicating that they are derived from linolenic or linoleic acid, respectively (Rule and Roelofs, 1989;

Millar, 2000). Linolenic and linoleic acid cannot be biosynthesized by moths so they must be obtained from the diet (Stanley-Samuelson *et al*., 1988). A few even-chain-length hydrocarbon sex pheromones have been identified that also have 3,6,9- or 6,9-double bond configurations (Millar, 2000), indicating that they too are derived from linolenic or linoleic acids; however, it is not known how these even-chain hydrocarbons are formed.

A major class of sex pheromones that are derived from hydrocarbons are the polyene monoepoxides (Millar, 2000). These usually have double bonds in the 3,6,9-positions or 6,9-positions, again indicating that they are biosynthesized from linolenic or linoleic acids, respectively. Although the production of hydrocarbon occurs in oenocytes the epoxidation step takes place in the pheromone gland. This has been demonstrated in several studies utilizing deuterium labeled precursors. In a study on the Japanese giant looper, *Ascotis selenaria cretacea*, that uses 6,9–19:3,4Epox as a sex pheromone component, deuterium-labeled hydrocarbon precursor, D3–3,6,9–19:Hc, was topically applied to pheromone glands and found to be converted to the epoxide, indicating that epoxidation takes place in pheromone glands (Miyamoto *et al*., 1999). By using a variety of polyene precursors, it was also determined that the monooxygenase regiospecifically attacked the *n*-3 double bond regardless of chain length or degree of unsaturation. This indicates that the epoxidation enzyme is regiospecific in this insect (Miyamoto *et al*., 1999).

A study using the gypsy moth, *L. dispar*, illustrates the overall pathways involved in production of epoxide pheromone components (**Figure 6**) (Jurenka *et al*., 2003). This insect uses disparlure, 2me-18:7,8Epox, as a pheromone component. Incubation of isolated abdominal epidermal tissue with deuterium-labeled valine resulted in incorporation into 2me-*Z*7–18:Hc. This indicates that the oenocyte cells associated with the epidermal tissues biosynthesize 2me-*Z*7–18:Hc using the carbons of valine to initiate the chain. The double bond is probably introduced by a Δ12-desaturase as determined by using specific deuterium-labeled intermediates. Hemolymph transport of 2me-*Z*7–18:Hc is indicated by the finding of this alkene in the hemolymph (Jurenka and Subchev, 2000). Demonstration that 2me-*Z*7–18:Hc is converted to the epoxide in the pheromone gland was shown by using deuterium-labeled 2me-*Z*7–18:Hc and incubation with isolated pheromone glands. Disparlure is a stereoisomer that has the 7*R*,8*S* or (+) configuration and chiral chromatography indicated that only the (+)-isomer was produced by pheromone glands (Jurenka *et al*., 2003). These results indicate that hydrocarbon pheromones and their epoxides are produced through a pathway outlined in **Figure 6**.

3.14.4.4. Pheromone Biosynthesis in Beetles

Pheromone biosynthesis in the Coleoptera is as diverse as the taxa and the pheromone structures, and the utilization of several types of pheromone biosynthetic pathways has been demonstrated (Vanderwel and Oehlschlager, 1987; Vanderwel, 1994; Seybold and Vanderwel, 2003; Tittiger, 2003). Extensive work has been done on the biosynthesis of coleopteran pheromones, and the major

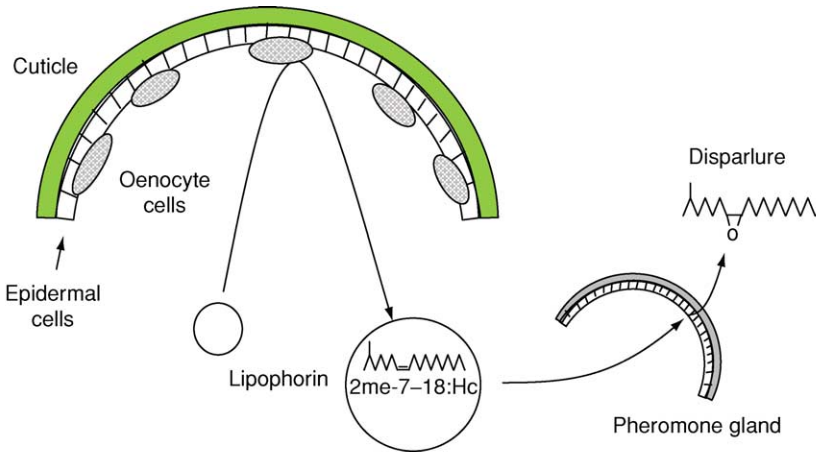

Figure 6 Production of the sex pheromone in the gypsy moth, *Lymantria dispar*. The oenocyte cells located in the abdomen biosynthesize the alkene hydrocarbon precursor to the pheromone, 2me-*Z*7–18:Hc. It is transported through the hemolymph by lipophorin. The alkene is taken up by pheromone gland cells where it is acted upon by an epoxidase to produce the pheromone disparlure, 2me-18:7,8Epox. (Reprinted with permission from Jurenka, R.A., **2003**. Biochemistry of female moth sex pheromones. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Elsevier, San Diego, CA, pp. 53–80; © Elsevier.)

systems that have been investigated are described below. Beetles can generate pheromone either by modification of dietary host compounds or *de novo* biosynthesis, with the latter accounting for the majority of beetle pheromone components.

3.14.4.4.1. Isoprenoid pheromones from bark beetles Most of the knowledge about beetle pheromone biosynthesis and endocrine regulation (see Section 3.14.4.5.2) comes from studies of various bark beetles, especially *Ips* and *Dendroctonus* species (Scolytidae). Some bark beetles may modify fatty acyl or amino acid precursors (Vanderwel and Oehlschlager, 1987; Birgersson *et al*., 1990); however, the majority of pheromone components are isoprenoid (Schlyter and Birgarson, 1999: Seybold *et al*., 2000).

Understanding of the origin of bark beetle pheromone components has undergone a paradigm shift in the last decade. Until recently, it was widely accepted that bark beetles, in contrast to most other insects (Tillman *et al*., 1999), obtained their pheromone components by simple modification of of host tree dietary precursors (reviews: Bordon, 1985; Vanderwel and Oelschlager, 1987; Vanderwel, 1994). This model was based on various studies that showed the association of monoterpene synthesis with conifers (Croteau, 1981), the abundance of potential precursors in the host tree (Gershenzon and Croteau, 1991), the demonstration that monoterpenoid precursors such as myrcene and α-pinene could be converted to the pheromone components ipsdienol, ipsenol, and *cis* and *trans* verbenol (Hughes, 1974; Renwick *et al*., 1976a, 1976b; Byers, 1981), and the conclusive demonstration that deuterated myrcene was converted to ipsenol and ipsdienol in *I. paraconfusus* (Hendry *et al*., 1980).

In the past decade and a half, however, significant evidence has emerged supporting the *de novo* biosynthesis of most bark beetle pheromone components. First, doubts were raised about the role of myrcene in ipsdienol and ipsenol production when it was noted that myrcene may not be present in sufficient quantity in some host trees to account for the amount of pheromone that was produced (Byers, 1981; Byers and Birgersson, 1990). Second, *Ips* beetles treated with the HMG-R reductase inhibitor compactin show a marked decrease in ipsdienol production (Ivarsson *et al*., 1993). Third, myrcene-treated male *I. pini* produce ipsdienol with a racemic enantiomeric composition whereas JH III-treated males produce ipsdienol with a 87–96% (−) enantiomeric composition (Lu, Blomquist, and Seybold, unpublished data). The naturally occurring enantiomeric composition of ipsdienol from California *I. pini* is 95–98% (−) (Seybold *et al*., 1995a). Fourth, JH III-treated male *I. pini* incorporate labeled acetate and mevalonate into ipsdienol (Seybold *et al*., 1995b; Tillman *et al*., 1998). 2-Methyl-3-buten-2-ol is similarly synthesized *de novo* in *I. typographus* (Lanne *et al*., 1989). More recently, key genes in pheromone production, including HMG-R and HMG-CoA synthase (HMG-S) have expression patterns consistent with their roles in regulating *de novo* isoprenoid pheromone biosynthesis (Tittiger *et al*., 1999; Tillman, Blomquist, and Seybold, unpublished data). A geranyl diphosphate synthase (GPPS) cDNA from *I. pini* was also isolated, functionally expressed, and modeled (Gilg-Young, Welch, Tittiger, and Blomquist, unpublished results). The existence of this novel enzyme argues strongly for the evolution of *de novo* pheromone biosynthetic capacity in bark beetles. Taken together, the data emerging from *Ips* species overwhelmingly indicate the *de novo* production of monoterpenoid pheromone components.

These data are supported by studies in other beetles that similarly prove or imply *de novo* pheromone component biosynthesis. Radiotracer studies demonstrated the *de novo* biosynthesis of frontalin in a number of *Dendroctonus* species (Barkawi *et al*., 2003). Expression patterns of HMG-R and HMG-S in *D. jeffreyi* correlate tightly with frontalin production (Tittiger *et al*., 2000, 2003). The four monterpene alcohols and aldehydes in the boll weevil, *A. grandis*, are also synthesized from mevalonate and acetate (Mitlin and Hedin, 1974; Thompson and Mitlin, 1979).

The capacity for *de novo* biosynthesis does not preclude the conversion of host precursors to pheromone components. For example, the incorporation of acetate and mevalonolactone into ipsdienol and ipsenol may proceed through the conversion of geranyl diphosphate to myrcene, which could be directly hydroxylated to ipsdienol and *E*-myrcenol, and indirectly, perhaps through a ketone intermediate, to ipsenol (Martin *et al*., 2003). In this scheme, host myrcene ingested during feeding would enter the *de novo* pathway downstream of geranyl diphosphate. Similarly, cotton plant monoterpenes (myrcene and limonene) could enter a *de novo* biosynthetic pathway to grandlure in *A. grandis*. The question then arises as to whether *de novo* biosynthesis or host precursor conversion is the preferred route to pheromone production. Male *I. pini* exposed to myrcene vapors produce a racemic mixture of ipsdienol, whereas the naturally occurring pheromone of Western *I. pini* is about 95 : 5 (−)/(+) ratio (Lu, Blomquist, and Seybold, unpublished data). This suggests that myrcene is not the

direct precursor to ipsdienol, but that its hydroxylation is a true detoxification reaction. Perhaps a highly specific hydroxylase may synthesize ipsdienol *de novo*, while a hydroxylase with a different specificity detoxifies myrcene. Other possibilities also exist, particularly considering that ipsdienone appears to be a precursor to ipsdienol (Ivarsson *et al.*, 1997). To make ipsdienol, it is possible that geranyl diphosphate is hydroxylated and then dephosphorylated, bypassing myrcene as an intermediate. Thus, though the final biosynthetic steps remain uncharacterized, *de novo* biosynthesis is clearly the most important route to ipsdienol and ipsenol in *I. pini* and *I. paraconfusus*. Further examples should arise as other species are studied.

A proposed biosynthetic scheme for a number of coleopteran isoprenoid pheromone components is presented in **Figure 7**. Hemiterpene pheromone components of the bark beetles are similarly synthesized *de novo*. Lanne *et al.* (1989) demonstrated the incorporation of labeled acetate, glucose, and mevalonate into 2-methyl-3-buten-2-ol in *I. typographus*. This also argues for the *de novo* synthesis of 3-methyl-3-buten-1-ol and 3-methyl-2-buten-1-ol.

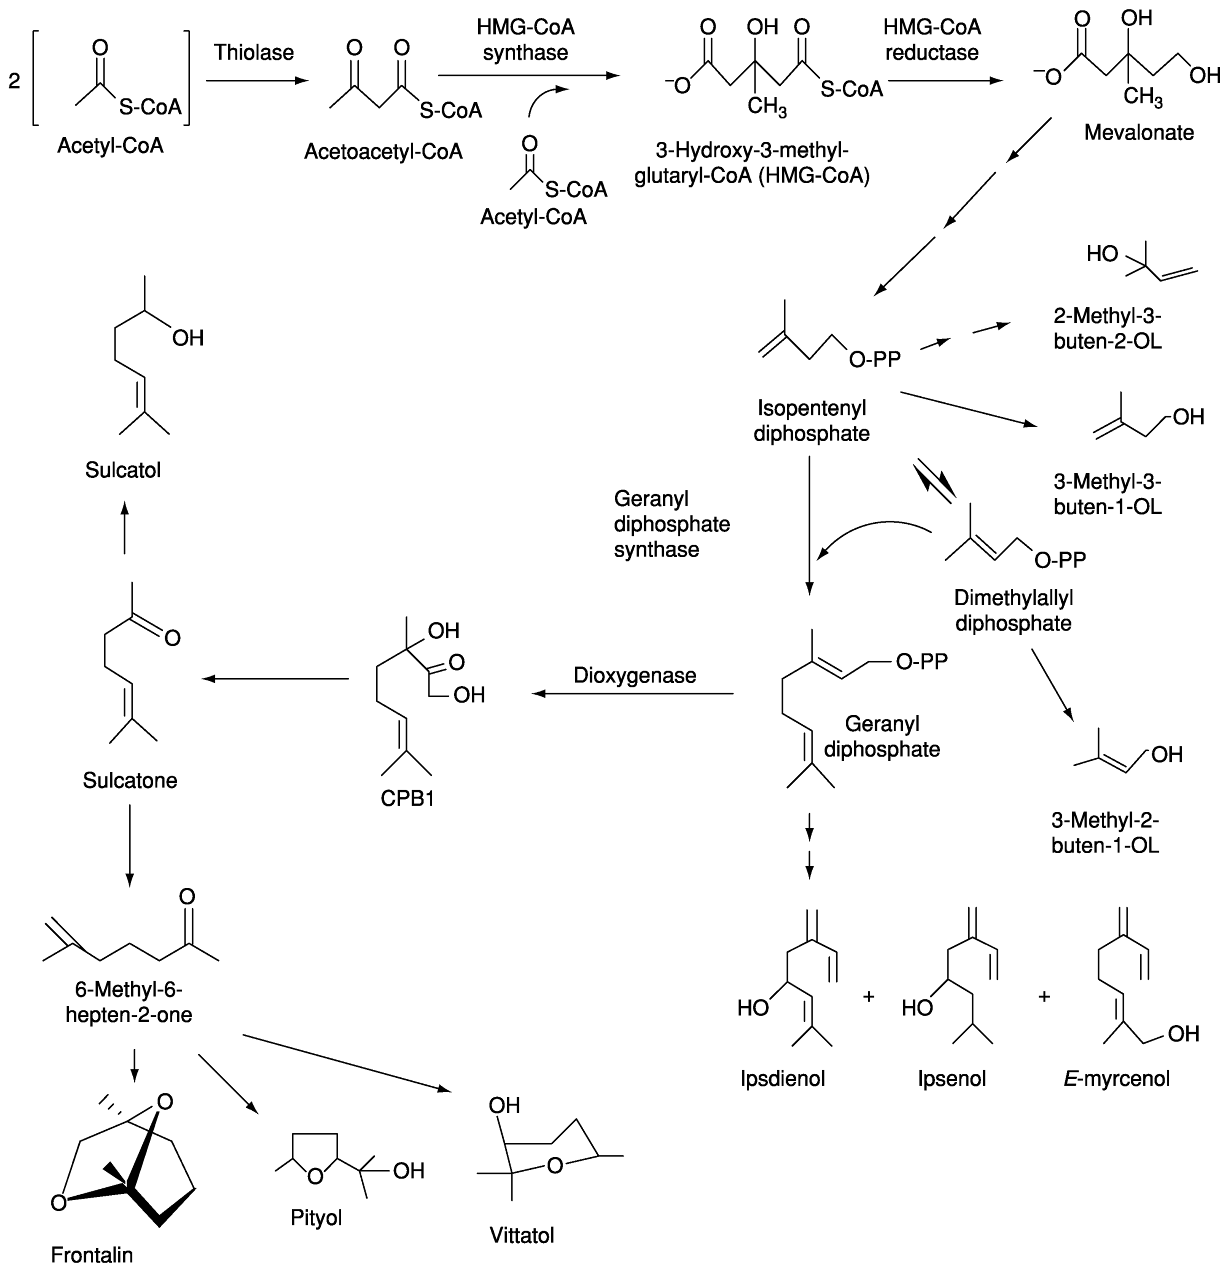

Figure 7 Proposed biosynthetic pathways for a number of hemi- and monoterpenoid pheromone components in the Coleoptera.

The mevalonate pathway intermediate, dimethylallyl diphosphate, likely provides the carbon skeleton for 3-methyl-2-buten-1-ol by dephosphorylation. The other five-carbon intermediate, isopentenyl diphosphate, could be directly converted to 3-methyl-3-buten-1-ol, and perhaps through several steps, to 2-methyl-3-buten-2-ol.

Ipsdienol and ipsenol production from geranyl diphosphate appears to involve relatively straightforward though not yet fully characterized biochemical modifications. The production of frontalin, and the recently identified male-produced pheromone of the Colorado potato beetle, *Leptinotarsa decemlineata* (*S*)-3,7-dimethyl-2-oxo-oct-6-ene-1,3-diol (CPB1) (Dickens *et al*., 2002), is less clear. Barkawi *et al*. (2003) demonstrated that acetate and mevalonolactone are precursors to frontalin, proving the isoprenoid origin of this common *Dendroctonus* pheromone component. he carbon skeleton of frontalin probably arises from geranyl disphosphate via a putative dioxygenase, which converts geranyl diphosphate to sulcatone. Sulcatone is an obvious precursor to sulcatol, which is a pheromone component of some bark beetles (*Gnathotrichus sulcatus*) (Byrne *et al*., 1974). In *Dendroctonus* spp., geranyl diphosphate-derived sulcatone may be converted to 6-methyl-6-hepten-2-one (6-MHO), a known intermediate to frontalin (Perez *et al*., 1996). Alternative cyclizations of 6-MHO in other beetles could lead to the pheromone components pityol and vittatol. Significant amounts of sulcatone are also found in Colorado potato beetle males during their synthesis of CPB1 (Dickens *et al*., 2002). It is easy to envision CPB1 as an intermediate in the dioxygenase reaction (**Figure 7**).

The picture emerging from these studies is that isoprenoid pheromone component production in beetles is mostly *de novo*, with carbon being diverted from the mevalonate pathway at geranyl diphosphate. Geranyl diphosphate may be directly modified through dephosphorylation and cyclizations (cotton boll weevil) or hydroxylations (*Ips* spp.). Alternatively, some bark beetles, such as *Dendroctonus* spp., apparently have a dioxygenase that oxidizes geranyl diphosphate or geraniol to produce a ketodiol (CPB1) or sulcatone, which acts as a precursor to some pheromone components such as sulcatol, pityol, and frontalin.

3.14.4.4.2. Fatty acid-derived pheromones Numerous beetle genera use modified fatty-acyl compounds as pheromone components. Less is known about their biosynthesis compared to that of isoprenoid pheromones, but the same general strategy of modifying or combining existing biosynthetic pathways is conserved.

For some beetles, the modifications are relatively minor. For example, *Attagenus* spp. (Dermestidae) myristic acid may be desaturated at the Δ5 and Δ7 positions to produce tetradecadienoic acid pheromone components. The stereochemistries of the double bonds apparently provide specificity between species (Fukui *et al*., 1977). It is unclear whether the short-chain fatty acid precursors to these pheromone components are synthesized through normal fatty acid elongations, or are the β-oxidation products of longer fatty acids. For other beetles, modifications can become more complex. Female *Tenebrio molitor* produce 4-methyl-1-nonanol from propionyl-, malonyl-, and methylmalonyl-precursors (Islam *et al*., 1999). This is an example of carbon being shunted away from fatty-acyl elongation before long fatty acids are completed. The use of methylmalonate to produce methyl-branched hydrocarbons is well established in other insect systems (Blomquist, 2003; Schal *et al*., 2003), though it is unknown if beetles have a secondary fatty acyl synthase which, similar to that in houseflies, incorporates methylmalonyl-CoA precursors efficiently.

The flexibility of the fatty acid biosynthetic pathway is extended in some nitidulid beetles (*Carpophilus* spp.), where males use propionate and butyrate (presumably as methylmalonate and ethylmalonate) to make methyl- and ethyl-branched triene and tetraene pheromone components (**Figure 1**), apparently also via the fatty acid biosynthetic pathway (Bartelt *et al*., 1992). The branched hydrocarbons generally have 10–12 carbon backbones with conjugated double bonds. In contrast to other systems, where pheromone component biosynthesis is highly specific, *Carpophilus* spp. males produce a mixture of related structures, some of which act as pheromones and some of which do not. Since di-substituted tetraenes are less abundant than mono- or unsubstituted tetraenes, it appears that nonacyl units placed in the growing hydrocarbon chains represent "mistakes" made by a synthesis machinery with a low stringency for substrate selection (Bartelt, 1999). Such nonspecific hydrocarbon biosynthesis may serve speciation, since changes in antennal receptivity may accommodate preexisting compounds (Bartelt, 1999). Interestingly, the desaturated nature of these hydrocarbons is not due to fatty acyl desaturases, but due to the inactivity of enoyl-ACP reductase during biosynthesis so that the enoyl-ACP intermediate formed during elongation is not reduced (Petroski *et al*., 1994). This

suggests that carbon is shunted out of the fatty acid biosynthetic pathway when the chains are of the correct length, similar to the situation in *T. molitor.*

Rather than modifying the normal biosynthetic pathway to produce pheromone components, some beetles modify normal products of the pathway. For example, lactone pheromone components of some scarab beetles are produced by the stereospecific alterations of long chain fatty acids. Female *Anomala japonica* (Scarabaeidae) are perhaps best studied among scarab beetles for the biosynthesis of japonilure and buibuilactone, which involves the successive Δ9 desaturation, hydroxylation, two rounds of β-oxidation to shorten the chain length, and cyclization of stearic and palmitic acids (Leal *et al.*, 1999). Of all these, only the hydroxylation step appears to be stereospecific (Leal, 1998). This step is important because different enantiomers have different functions in different *Anomala* species (Leal *et al.*, 1999).

3.14.4.4.3. Host precursor modifications While most bark beetle isoprenoid pheromones are clearly synthesized *de novo*, there is strong evidence that some pheromone components are indeed the result of modifying host precursor molecules. α-Pinene is produced naturally by pine trees, and can be hydroxylated to *cis-* and *trans-*verbenol (**Figure 1**) by *Ips* beetles (Renwick *et al.*, 1976a). A further oxidation of verbenol yields verbenone in *Dendroctonus ponderosae* (Hunt and Bordon, 1989). Similarly, Jeffrey pine trees contain relatively low levels of monoterpenoids, but high levels of heptane. Female *Dendroctonus jeffreyi* that attack these trees produce 1-heptanol and 2-heptanol, and 1-heptanol acts as a sex pheromone (Paine *et al.*, 1999).

3.14.4.5. Pheromone Biosynthesis in Diptera

3.14.4.5.1.1. Housefly pheromone biosynthesis: C23 sex pheromone components A combination of *in vivo* and *in vitro* studies using both radio- and stable-isotope techniques established the biosynthetic pathways for the major sex pheromone components in the housefly (**Figure 8**) (Dillwith *et al.*, 1981, 1982; Dillwith and Blomquist, 1982; Blomquist *et al.*, 1984b; Vaz *et al.*, 1988). (*Z*)-9-tricosene is formed by the microsomal elongation of 18:1-CoA to 24:1-CoA using malonyl-CoA and NADPH, and the elongated fatty acyl-CoA is then reduced to the aldehyde and converted to the hydrocarbon one carbon shorter (**Figure 8**) (Reed *et al.*, 1994, 1995; Mpuru *et al.*, 1996). A cytochrome P450 enzyme is involved in the metabolism of the alkene to the corresponding epoxide and ketone (Ahmad *et al.*, 1987). It appears that the same enzyme that catalyzes formation of an epoxide from the double bond between carbons 9 and 10 of the alkene of (*Z*)-9-tricosene also hydroxylates it at position *n*-10. The secondary alcohol thus formed is then converted to the unsaturated ketone (Guo *et al.*, 1991).

3.14.4.5.1.2. Mechanism of hydrocarbon formation: decarboxylation? The mechanism of hydrocarbon formation has proven elusive. In an elegant set of experiments in the 1960s and early 1970s, Kolattukudy and coworkers demonstrated that fatty acyl-CoAs were elongated and then converted to hydrocarbon by the loss of the carboxyl group (reviews: Kolattukudy *et al.*, 1976; Kolattukudy, 1980). In the 1980s and early 1990s, the hypothesis was put forward that very long chain fatty acyl-CoAs were reduced to aldehyde and then decarbonylated to hydrocarbon and carbon monoxide, and that this reaction did not require any cofactors or O_2. Evidence for this decarbonylation mechanism was obtained from a plant (Cheesbrough and Kolattukudy, 1984), an alga (Dennis and Kolattukudy, 1991, 1992), a vertebrate (Cheesbrough and Kolattukudy, 1988), and an insect (Yoder *et al.*, 1992).

In the work on hydrocarbon formation in the housefly, it was found that the acyl-CoA is reduced to the aldehyde, with the conversion of the aldehyde to hydrocarbon requiring NADPH and molecular oxygen, and that the products were hydrocarbon and carbon dioxide (demonstrated by radio-gas–liquid chromatography) (Reed *et al.*, 1994, 1995). Antibodies to housefly cytochrome P450 and to P450 reductase inhibited hydrocarbon formation in microsomes, as did exposure to CO, and the latter could be partially reversed by white light. GC-MS analyses of specifically deuterated substrates showed that the protons on positions 2,2 and 3,3 of the acyl-CoA were retained during conversion to hydrocarbon, and that the proton on position 1 of the aldehyde was transferred to the adjacent carbon and retained during hydrocarbon formation. Furthermore, several peroxides could substitute for O_2 and NADPH and support hydrocarbon production. All this evidence strongly supports a cytochrome P450 involvement in hydrocarbon synthesis (Reed *et al.*, 1994).

The mechanism of hydrocarbon formation remains controversial, with evidence obtained favoring both a decarbonylation and a decarboxylation mechanism. The resolution of the problem awaits cloning, expressing, and assaying the enzymes involved.

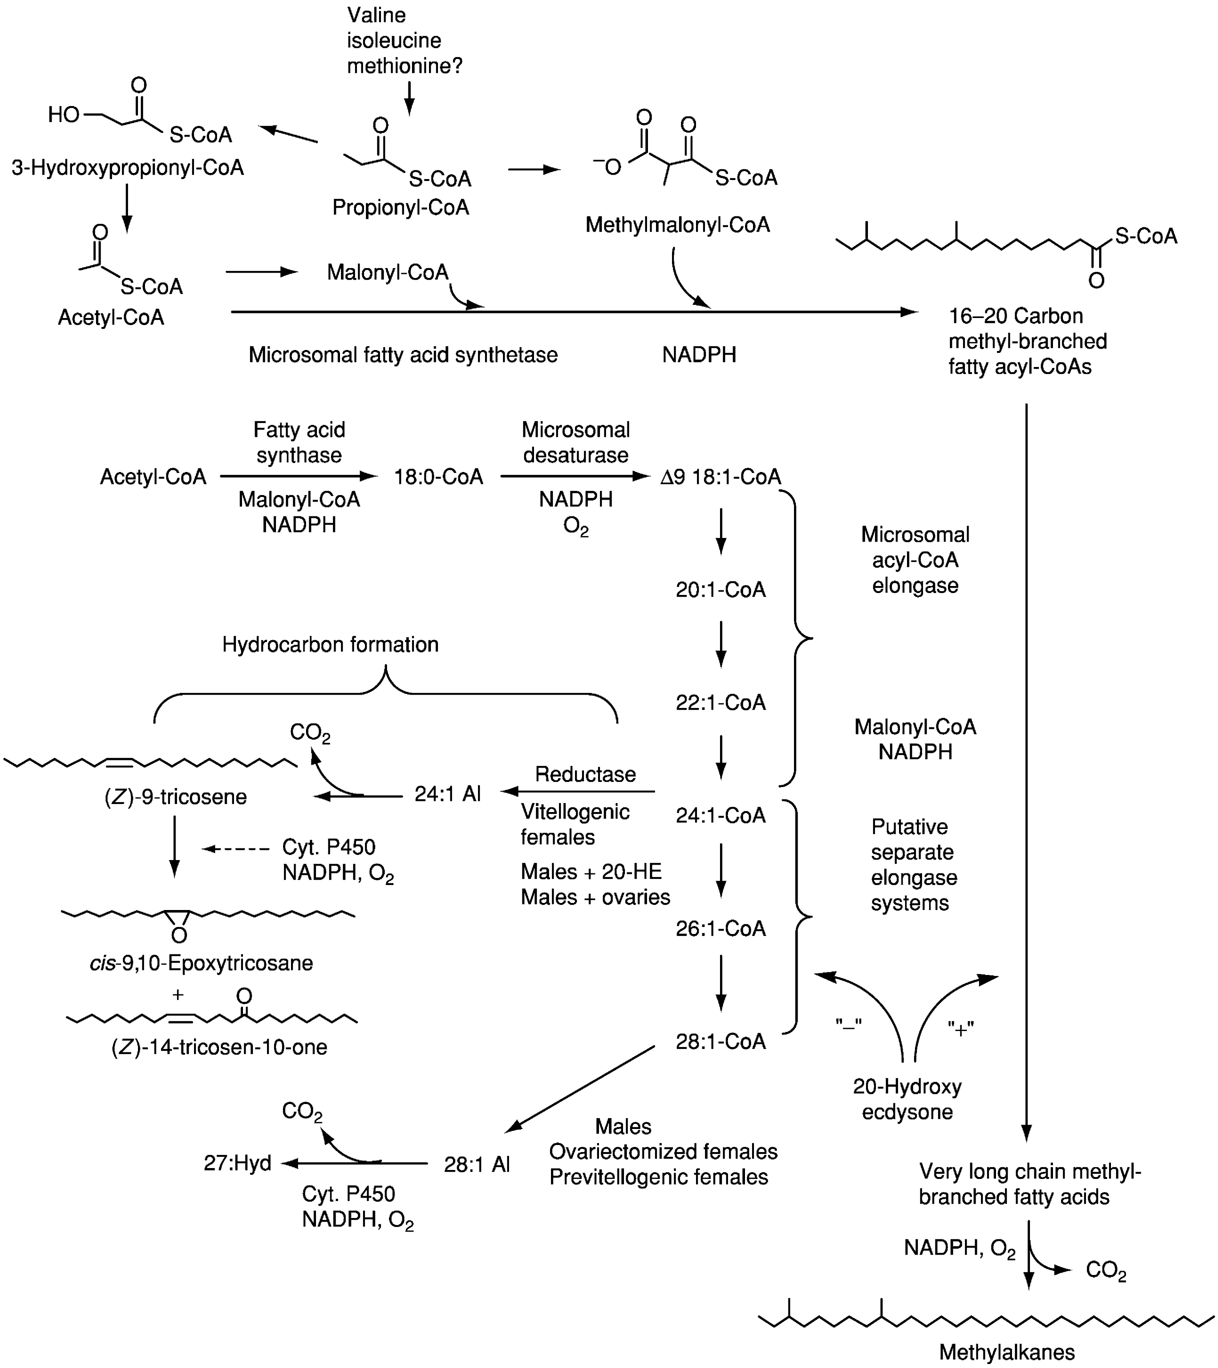

Figure 8 Biosynthetic pathways showing the putative steps at which ecdysteroids regulate the hydrocarbon and hydrocarbon-derived pheromone components of the female housefly, *Musca domestica*. (Reprinted with permission from Blomquist, G.J., **2003**. Biosynthesis and ecdysteroid regulation of housefly sex pheromone production. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Elsevier, New York, pp. 131–252; © Elsevier.)

3.14.4.5.1.3. Biosynthesis of the methylalkane pheromone components Methylalkanes are formed by the substitution of methylmalonyl-CoA in place of malonyl-CoA at specific points during chain elongation. Carbon-13 nuclear magnetic resonance (NMR), mass spectrometry, and radiochemical studies (Dwyer *et al.*, 1981; Dillwith *et al.*, 1982; Chase *et al.*, 1990) demonstrated that the methylmalonyl-CoA was added during the initial steps of chain elongation in insects using what appears to be a novel microsomal fatty acid synthase (FAS) (Figure 8). A microsomal FAS was

first suggested from studies on *T. ni* for the formation of methyl-branched very long chain alcohols (de Renobales *et al*., 1989). In this insect, high rates of methyl-branched very long chain alcohol synthesis were observed in the mid-pupal stages at times when soluble FAS activity was very low or undetectable. The FAS of most organisms is soluble (cytoplasmic).

A microsomal FAS was also implicated in the biosynthesis of methyl-branched fatty acids and methyl-branched hydrocarbon precursors of the German cockroach contact sex pheromone (Juarez *et al*., 1992; Gu *et al*., 1993). A microsomal FAS present in the epidermal tissues of the housefly is a likely candidate responsible for methyl-branched fatty acid production (Blomquist *et al*., 1994). The housefly microsomal and soluble FASs were purified to homogeneity (Gu *et al*., 1997) and the microsomal FAS was shown to preferentially use methylmalonyl-CoA in comparison to the soluble FAS. GC–MS analyses showed that the methyl-branching positions of the methyl-branched fatty acids of the housefly (Blomquist *et al*., 1994) were in positions consistent with them being the precursors of the methyl-branched hydrocarbons.

The methylmalonyl-CoA unit that is the precursor to methyl-branched fatty acids and hydrocarbons arises from the carbon skeletons of valine and isoleucine, but not succinate (Dillwith *et al*., 1982). Propionate is also a precursor to methylmalonyl-CoA, and in the course of these studies, a novel pathway for propionate metabolism in insects was discovered. Many insect species, including the housefly, do not contain vitamin B_{12} (Wakayama *et al*., 1984), and therefore cannot catabolize propionate via methylmalonyl-CoA to succinate. Instead, as first demonstrated in the housefly (Dillwith *et al*., 1982), insects metabolize propionate to 3-hydroxypropionate and then to acetyl-CoA, with carbons 3 and 2 of propionate becoming carbons 1 and 2 of acetyl-CoA (**Figure 8**) (Halarnkar *et al*., 1986).

3.14.4.5.2. Pheromone biosynthesis in *Drosophila*
The other major dipteran system in which pheromone production has been extensively studied is that of *Drosophila*. Jallon and Wicker-Thomas (2003) provide an excellent and detailed review of the chemistry, biochemistry, molecular biology, and genetics of pheromone production in *Drosophila*. *Drosophila*, as do *Musca*, use long chain, sex-specific hydrocarbons as close range and contact sex pheromones. *Drosophila melanogaster* Canton-S mature females have abundant (*Z*,*Z*)-7,11-heptacosadiene, which is absent on males and was shown to effectively stimulate wing vibration in conspecific males when applied to a dummy (Antony and Jallon, 1982; Ferveur and Sureau, 1996). In some *Drosophila*, 7-tricosene is involved in chemical communication. A series of studies established that the hydrocarbon pheromones are produced in the oenocytes (Ferveur *et al*., 1997), transported through the hemolymph via lipophorin (Pho *et al*., 1996), and then deposited on the cuticle.

A series of experiments assaying the incorporation of various precursors into hydrocarbons established that *Drosophila* use an elongation–decarboxylation pathway for hydrocarbon production (Pennanec'h *et al*., 1997). An interesting question in *Drosophila* pheromone production is the origin of the 7,11 double bonds. Biochemical evidence suggested that either a Δ7-desaturase working on myristate, or a Δ9-desaturase working on palmitate give rise to the double bond in the 7-position, which could then be elongated to produce vaccenate (*n*-7, 18 : 1). Vaccenate could then be elongated and decarboxylated to produce 7-tricosene, and, with an additional desaturation step, to produce 7,11-27:2Hyd.

Wicker-Thomas *et al*. (1997) isolated a cDNA encoding a desaturase (*desat1*) in *D. melanogaster*. The expressed *desat1* protein is a Δ9-desaturase that preferentially used palmitate, resulting in *n*-7 fatty acids. A *desat2*, located close to *desat1*, appears to be responsible for the 5,9-dienes present in Tai females (Jallon and Wicker-Thomas, 2003). The identification of the desaturase genes responsible for pheromone production in fruit flies will greatly benefit from the characterization of the *D. melanogaster* genome. Understanding of the genetics combined with molecular biology undoubtedly will result in a more complete understanding of the mechanisms and genes involved and regulated in pheromone production in *Drosophila*.

3.14.4.6. Biosynthesis of Contact Pheromones in the German Cockroach

Upon antennal contact with a female, the male German cockroach rotates his body 180° and raises his wings, thus exposing specialized tergal glands that attract the female and place her into a precopulatory position (Nojima *et al*., 1999). The nonvolatile contact pheromone responsible for this behavior was identified as (3*S*,11*S*)-dimethylnonacosan-2-one (**Figure 1**) (Nishida *et al*., 1974), and an alcohol (29-hydroxy-3*S*,11*S*-dimethylnonacosan-2-one) and an aldehyde (29-oxo-3,11-dimethylnonacosan-2-one) derivatives with the same 3,11-dimethylketone skeleton (Nishida and Fukami, 1983). A fourth pheromone component, 3,11-dimethylheptacosan-2-one, is less active than its C_{29} homolog (Schal *et al*., 1990b).

The route of biosynthesis and its physiological regulation have been reviewed previously (Blomquist *et al.*, 1993; Tillman *et al.*, 1999; Schal *et al.*, 2003). Central to investigations of the biosynthetic pathway was the observation that the major cuticular hydrocarbon in all life stages of the German cockroach is an isomeric mixture of 3,7-, 3,9- and 3,11-dimethylnonacosane (Jurenka *et al.*, 1989). The presence of only the 3,11-isomer in the cuticular dimethyl ketone fraction and only in adult females prompted Jurenka *et al.* (1989) to propose that production of the pheromone might result from the sex-specific oxidation of its hydrocarbon analog only in adult females. This scheme follows the well-established conversion of hydrocarbons to methyl ketone and epoxide pheromones in the housefly (see above) (Blomquist *et al.*, 1984b; Ahmad *et al.*, 1987).

This model has since been validated with several independent approaches. Biochemical studies on the biosynthesis of methyl-branched alkanes showed that the methyl branches are added during the early stages of chain elongation (Chase *et al.*, 1990). Using carbon-13 labeling and NMR analyses, Chase *et al.* (1990) showed that carbons 1 and 2 of acetate are incorporated as the chain initiator, and that the carbon skeleton of propionate serves as the methyl branch donor (**Figure 9**). Further, propionate and succinate labeled methyl-branched hydrocarbons and the methyl ketone pheromone, as did the amino acids valine, isoleucine, and methionine, all of which can be metabolized to propionate. NMR studies confirmed that these substrates were metabolized to methylmalonyl-CoA for incorporation into the methyl branch unit of hydrocarbons (Chase *et al.*, 1990), as in the housefly (Dillwith *et al.*, 1982; Halarnkar *et al.*, 1986), American cockroach (Halarnkar *et al.*, 1985), cabbage looper moth (de Renobales and Blomquist, 1983), and the termite *Zootermopsis* (Chu and Blomquist, 1980).

Methyl-branched fatty acids are intermediates in branched alkane biosynthesis (Juarez *et al.*, 1992). Thus, [$^{14}C_1$]propionate labeled methyl-branched fatty acids of 16–20 carbons, but did not label straight-chain saturated and monounsaturated fatty acids (Chase *et al.*, 1990).

Chase *et al.* (1992) investigated the hypothesis that the 3,11-dimethyl ketone sex pheromone arises from the insertion of an oxygen into the preformed 3,11-dimethyl alkane. When high-specific activity, tritiated 3,11-dimethylnonacosane (mixture of stereoisomers), was topically applied on the cuticle of *B. germanica* females, it readily penetrated the cockroach and radioactivity from the alkane was detected in both 3,11-dimethylnonacosan-2-ol and 3,11-dimethylnonacosan-2-one. Likewise, when tritiated 3,11-dimethylnonacosan-2-ol was applied to the cuticle it was readily and highly efficiently converted to the corresponding methyl ketone pheromone. But, surprisingly, the dimethyl ketone pheromone was derived from the corresponding alcohol not only in females, as expected, but also in males. These results suggest that the sex pheromone of *B. germanica* arises via a female-specific hydroxylation of 3,11-dimethylnonacosane and a subsequent nonsex-specific oxidation, probably involving a polysubstrate monooxygenase system, to the (3*S*,11*S*)-dimethylnonacosan-2-one pheromone (**Figure 9**). Chase *et al.* (1992) also suggested that a similar hydroxylation and subsequent oxidation at the 29-position of 3,11-dimethylnonacosan-2-one might give rise to 29-hydroxy- and 29-oxo-(3,11)-dimethylnonacosan-2-one, the other components of the contact pheromone blend, but this hypothesis has yet to be tested. It is quite likely, as well, that the same mechanism converts 3,11-dimethylheptacosane to the corresponding methyl ketone pheromone, and perhaps its 27-hydroxy- and 27-oxo- analogs.

The contact sex pheromone of female *B. germanica* remains the only cockroach pheromone whose biosynthetic pathway has been investigated with radio- and stable-isotope tracers.

3.14.4.7. Biosythesis of the Honeybee Queen Pheromone

The queen substance used for "queen control" inside the nest is also the substance used by virgin queens to attract drones for mating. It is the best understood of the sexual pheromones of the social insects. Callow and Johnston (1960) and Barbier and Lederer (1960) identified ([*E*]-9-oxodec-2-enoic acid) (9-ODA) in queen mandibular glands. 9-Hydroxy-2(*E*)-decenoic acid (9-HDA) is also present (Callow *et al.*, 1964) and together both attract drones. Recent work (Keeling *et al.*, 2003) identified a number of additional compounds that function synergistically with the 9-ODA and 9-HDA, making this the most complex pheromone blend known for any organism.

In an elegant set of experiments, Plettner *et al.* (1996, 1998) elucidated the biosynthetic pathways for the honeybee queen mandibular pheromone (QMP) components 9-ODA and 9-HDA and compared their biosyntheses to that of worker produced 10-hydroxy-2(*E*)-decenoic acid and the corresponding diacid. Using carbon-13 and deuterated precursors, Plettner *et al.* (1996, 1998) demonstrated (1) the *de novo* synthesis of stearic acid in worker mandibular glands, (2) the hydroxylation of

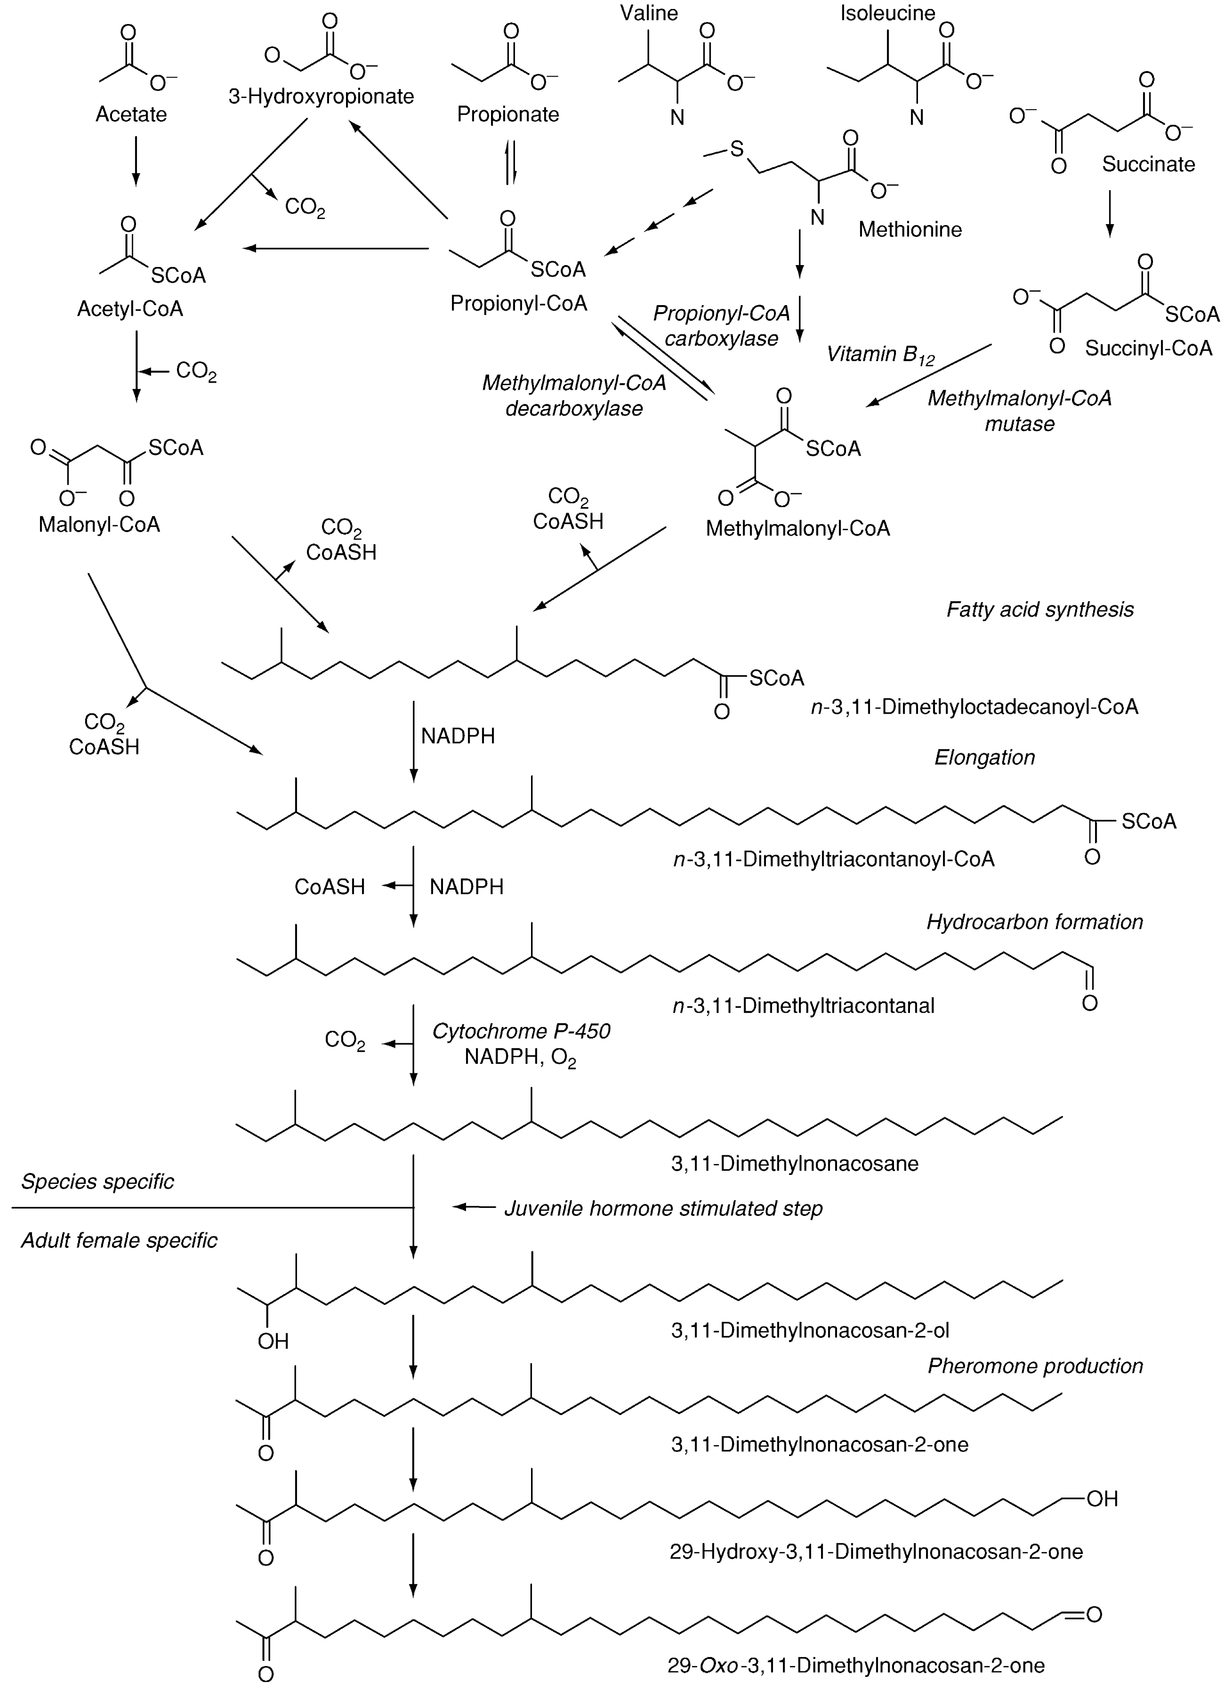

Figure 9 Proposed biosynthetic pathways for the major pheromone components of the German cockroach, *Blattella germanica*. The JH III regulated step appears to be the hydroxylation of the dimethylalkane.

stearic acid at the *n*-(workers) and *n*-1 (queens) positions, (3) chain shortening through β-oxidation to the 10- and 8-carbon hydroxy acids, and (4) oxidation of *n*- and *n*-1 hydroxy groups to give diacids and 9-keto-2(*E*)-decenoic acid, respectively. Stearic acid was shown to be the main precursor of the pheromone molecules as it was converted to C_{10} hydroxy acids and diacids more efficiently than either 16 or 14 carbon fatty acids.

3.14.5. Endocrine Regulation of Pheromone Production

3.14.5.1. Barth's Hypothesis

Juvenile hormone's central role in mate-finding was recognized in 1965 when Barth proposed that neuroendocrine control of pheromone production would be common in insects with a long-lived adult stage and with multiple reproductive cycles interrupted by periods during which sexual receptivity and mating are not appropriate or not even possible anatomically. Cockroaches and beetles are quintessential examples of this life-history syndrome. Conversely, in insects that eclose with mature oocytes, and live for only a few days as adults, Barth (1965) predicted that pheromone signaling would be part of the adult metamorphic process and not subject to neuroendocrine control. The discovery of PBAN in moths (see Section 3.14.4.5.2) appeared in conflict with this hypothesis, but Barth's model (Barth and Lester, 1973) clearly accounted for cases in moth species where adults feed and oocyte maturation requires the participation of JH or other neuroendocrine factors. Schal *et al.* (2003) proposed a reconsideration of the hypothesis, taking into account the coordination of reproductive developmental processes with mating-related events. Accordingly, in long-lived insects, such as cockroaches, pheromone production is expected to be synchronously regulated with other reproductive processes by the same hormone, usually JH. Cellular remodeling of the pheromone glands plays a prominent role in this group of insects, resulting in a slow stimulation of pheromone production. The cessation of pheromone production after mating is also slow, and precise control of pheromone signaling, therefore, is not at the level of pheromone production, but rather at the behavioral level through control of pheromone emission during calling. Conversely, in short-lived moths rapid modulation of rate-limiting enzymes in the pheromone biosynthetic pathway is much more prominent than developmental processes, and pheromone biosynthesis is turned on or off in coordination with activity cycles (day versus night) and sexual receptivity (virgin versus mated). Control of sexual signaling occurs at the level of pheromone production as well as emission, but these two events are usually regulated by different factors. Thus, both groups of insects exhibit neuroendocrine control of pheromone production. In cockroaches, pheromone production is coordinated with the gonotrophic cycle and the major gonadotropic hormone – JH – has been recruited to control both by acting at several target tissues. In most moths, alternatively, reproduction and pheromone production are regulated by different hormones. But here also, the hormones that control pheromone production (e.g., PBAN) also affect other target tissues such as myotropins, melanization agents, and diapause and pupariation factors. An interesting departure from the moth model occurs in migratory moth species in which reproduction is delayed by migration (low levels of JH production and sexual inactivity), and pheromone production and its release are JH dependent (Cusson *et al.*, 1994). All these observations are consistent with our interpretation of Barth's model.

The three hormones that regulate pheromone production in insects are shown in **Figure 2** and **Table 1**. PBAN has been studied in female moths and alters enzyme activity through second messengers at one or more steps during or subsequent to fatty acid synthesis during pheromone production (Rafaeli and Jurenka, 2003). In contrast, 20E and JH induce or repress the synthesis of specific enzymes at the transcription level. The action of JH has been studied most thoroughly in the German cockroach and in bark beetles, and this work is discussed below. Ecdysteroid regulation of pheromone production occurs in Diptera, and has been most extensively studied in the housefly, *M. domestica*.

3.14.5.2. PBAN Regulation in Moths

3.14.5.2.1. PBAN Most female moths release sex pheromones in a typical calling behavior in which the pheromone gland is extruded to release pheromone during a particular time of the photoperiod. In most cases pheromone biosynthesis coincides with calling behavior and the synchronization of these events is achieved by neuroendocrine mechanisms present in the female that in turn are influenced by various environmental and physiological events such as temperature, photoperiod, host plants, mating, hormones, neurohormones, and neuromodulators. We now know that the main neuroendocrine mechanism that regulates pheromone production in moths is pheromone biosynthesis activating neuropeptide (PBAN).

[a]Identified from the amino acid sequence of a purified peptide.
[b]Deduced from the cloned gene sequence.

The neuropeptide PBAN was localized to the subesophageal ganglion (SEG) (Raina and Menn, 1987), which facilitated purification and sequencing (Kitamura *et al.*, 1989; Raina *et al.*, 1989). The first PBAN identified had 33 amino acids with a C-terminal amidation and the core sequence FXPRLamide (where X represents S, T, G, or V) is required for activity, which places PBAN in a family of peptides with the C-terminal FXPRLamide motif (**Table 1**). The first member of this family to be identified was called leucopyrokinin based on its ability to stimulate hindgut contraction in the cockroach *Leucophaea maderae* (Holman *et al.*, 1986). Additional functions for this family include induction of embryonic diapause in *B. mori* (Imai *et al.*, 1991), induction of melanization in lepidopteran larvae (Matsumoto *et al.*, 1990), and acceleration of puparium formation in several flies (Zdarek *et al.*, 1998). In addition it was determined that the white shrimp, *Penaeus vannamei*, has two peptides that can induce myotropic activity (Torfs *et al.*, 2001). These results demonstrate the ubiquity and multifunctional nature of this family of peptides.

Localization of PBAN-like immunoreactivity in the central nervous system of adult moths indicated that several neurons in the SEG contain PBAN-like activity. These were found as clusters along the ventral midline, one each in the presumptive mandibular, maxillary, and labial neuromeres (Kingan *et al.*, 1992). All three groups of neurons have axons that project into the corpus cardiacum (CC) (Kingan *et al.*, 1992; Davis *et al.*, 1996). Two pairs of maxillary neurons send processes within the SEG that include posterior projections into the paired ventral nerve cord (VNC) and travel its entire length to terminate in the terminal abdominal ganglion (TAG). Arborizations arising from these paired projections were found in each segmental ganglion (Davis *et al.*, 1996). In addition the segmental ganglia have neurons that contain PBAN-like activity and these neurons can release peptides into the hemolymph (Ma and Roelofs, 1995c; Davis *et al.*, 1996; Ma *et al.*, 1996).

3.14.5.2.2. Molecular genetics of PBAN The gene encoding PBAN was first characterized from *H. zea* and *B. mori* (Imai *et al.*, 1991; Davis *et al.*, 1992; Kawano *et al.*, 1992; Sato *et al.*, 1993; Ma *et al.*, 1994). The full-length cDNA was found to encode PBAN plus four additional peptide domains with a common C-terminal FXPRL sequence motif including that of the diapause hormone of *B. mori*. Three additional peptides with the common C-termini and sequence homology to those of *H. zea* and *B. mori* have been deduced from cDNA isolated from pheromone glands of *Mamestra brassicae* (Jacquin-Joly and Descoins, 1996), *H. assulta* (Choi *et al.*, 1998), *Agrotis ipsilon* (Duportets *et al.*, 1999), *Spodoptera littoralis* (Iglesias *et al.*, 2002), *H. armigera* (Zhang *et al.*, 2001), and *Adoxophyes* sp. (Lee *et al.*, 2001). The posttranslational processed peptides can be found in the SEG (Sato *et al.*, 1993; Ma *et al.*, 1996). The matrix-assisted laser desorption ionization (MALDI) MS data indicated that PBAN was found to a greater extent in the mandibular and maxillary clusters than in the labial cluster (Ma *et al.*, 2000). The other neuropeptides were found in all clusters. In addition some larger peptide fragments were found indicating alternative processing of the precursor protein (Ma *et al.*, 2000).

3.14.5.2.3. PBAN mode of action Through the development of a sensitive *in vitro* bioassay, studies on *H. armigera* and *H. zea* demonstrated that brain extracts and synthetic *H. zea* PBAN could stimulate the production of the main pheromone component (Soroker and Rafaeli, 1989; Rafaeli *et al.*, 1990, 1991, 1993; Rafaeli, 1994; Rafaeli and Gileadi, 1996). The response obtained was specific to the pheromone gland and independent of other abdominal tissues (Rafaeli, 1994; Rafaeli *et al.*, 1997b). Evidence has since accumulated regarding several other species of moths including *B. mori*, *Spodoptera litura*, *O. nubilalis*, *Plodia interpunctella*, and *Thaumetopoea pityocampa* (Arima *et al.*, 1991; Fónagy *et al.*, 1992; Fabriàs *et al.*, 1995; Ma and Roelofs, 1995b; Rafaeli and Gileadi, 1995a; Jurenka, 1996). In addition, functional and viable pheromone gland cell-clusters were obtained from the intersegmental membrane of *B. mori* using papain enzymatic digestion (Fónagy *et al.*, 2000).

The signal transduction events that occur after PBAN binds to a receptor have been studied in several model moth species (**Figure 10**). The main difference found between these species so far is whether or not 3′,5′,cyclic-AMP (cAMP) is used as a second messenger. In the case of the heliothines and several others, cAMP is a second messenger. Alternatively, cAMP is thought not to act in pheromone gland cells of *B. mori* and *O. nubilalis* (Fónagy *et al.*, 1992; Ma and Roelofs, 1995b). Instead, in these insects, it is thought that an increase in cytosolic calcium directly activates downstream events leading to stimulation of the biosynthetic pathway.

Extracellular calcium is essential for pheromonotropic activity in all moths studied to date (Fónagy *et al.*, 1992, 1999; Ma and Roelofs, 1995a; Matsumoto *et al.*, 1995). It is suggested that free calcium,

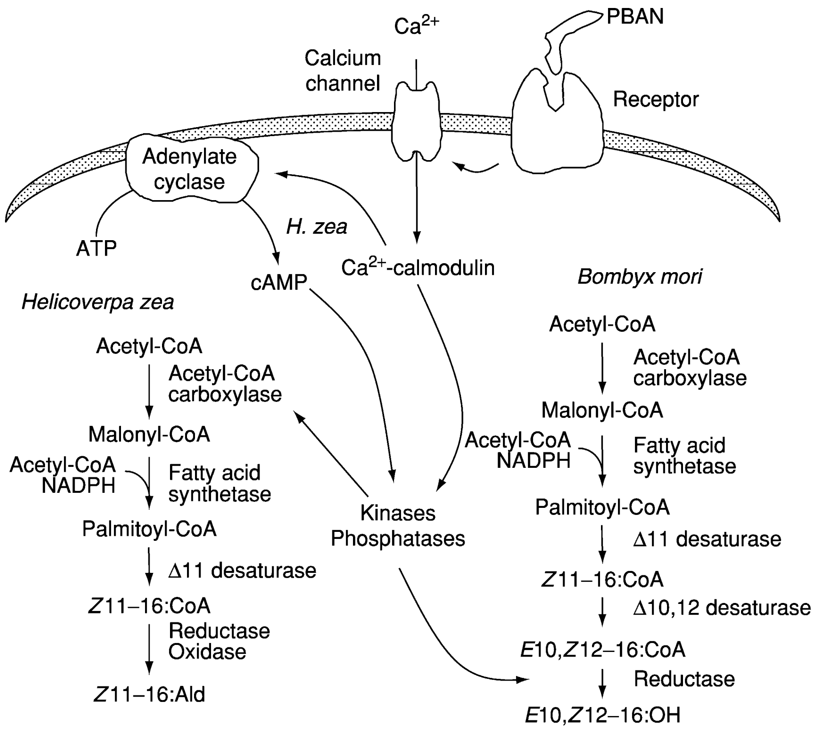

Figure 10 Proposed signal transduction mechanisms that stimulate the pheromone biosynthetic pathway in *Helicoverpa zea* and other heliothines as compared with that in *Bombyx mori*. It is proposed that PBAN binds to a receptor present in the cell membrane. Binding to the receptor somehow induces a receptor-activated calcium channel to open causing an influx of extracellular calcium. This calcium binds to calmodulin and in the case of *B. mori* will directly stimulate a phosphatase that will dephosphorylate and activate a reductase in the biosynthetic pathway. This activated reductase will then produce the pheromone bombykol. In *H. zea* and other heliothines like *H. armigera* the calcium-calmodulin will activate adenylate cyclase to produce cAMP that will then act through kinases and/or phosphatases to stimulate acetyl-CoA carboxylase in the biosynthetic pathway. (Reprinted with permission from Rafaeli, A., Jurenka, R.A., **2003**. PBAN regulation of pheromone biosynthesis in female moths. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Elsevier, San Diego, CA, pp. 107–136; © Elsevier.)

entering the cell, binds to calmodulin to form a complex thereby activating adenylate cyclase and/or phosphoprotein phosphatases (**Figure 10**). Calmodulin was characterized from pheromone glands of *B. mori* (Iwanaga *et al.*, 1998) and was shown to have an identical amino acid sequence to *Drosophila* calmodulin (Smith *et al.*, 1987). In *B. mori*, it is suggested that the Ca^{2+}/calmodulin complex directly or indirectly activates a phosphoprotein phosphatase (Matsumoto *et al.*, 1995). This phosphatase will then activate an acyl-CoA reductase in the biosynthetic pathway. Two genes encoding calcineurin heterosubunits were identified from the pheromone gland of *B. mori* and were found to be homologous to the catalytic subunit and regulatory subunits of other animal calcineurins (Yoshiga *et al.*, 2002). The calcineurin complex will apparently dephosphorylate an acyl-CoA reductase, which catalyzes the formation of bombykol in *B. mori*.

3.14.5.2.4. Enzymes affected in the pheromone biosynthetic pathway PBAN has been shown to stimulate the reductase that converts an acyl-CoA to an alcohol precursor (**Figure 10**) in several moths including *B. mori* (Arima *et al.*, 1991; Ozawa *et al.*, 1993), *T. pityocampa* (Gosalbo *et al.*, 1994), *S. littoralis* (Martinez *et al.*, 1990; Fabriàs *et al.*, 1994), and *M. sexta* (Fang *et al.*, 1995b; Tumlinson *et al.*, 1997). In *A. velutinana* (Tang *et al.*, 1989), *H. zea* (Jurenka *et al.*, 1991a), *Cadra cautella*, *S. exigua* (Jurenka, 1997) and *M. brassicae* (Jacquin *et al.*, 1994), it was demonstrated that PBAN controls pheromone biosynthesis by regulating a step during or prior to fatty acid biosynthesis (**Figure 10**). Circumstantial evidence in *A. segetum* (Zhu *et al.*, 1995) and *H. armigera* (Rafaeli *et al.*, 1990) also points to the regulation of fatty acid synthesis by PBAN. In one study using the moth *Sesamia nonagrioides* it was shown that the acetyltransferase enzyme might be regulated by PBAN (Mas *et al.*, 2000). There appears to be no particular pattern as to which enzyme within the pheromone biosynthetic pathway will be regulated by PBAN. However, in the majority of moths studied it is either the reductase or fatty acid synthesis that is stimulated.

Several families of moths utilize hydrocarbons and/or their epoxides as sex pheromones (Millar, 2000). It is thought that PBAN does not regulate the production of hydrocarbon sex pheromones as demonstrated in *Scoliopteryx libatrix* (Subchev and Jurenka, 2001). However, PBAN is probably regulating the production of epoxide sex pheromones. This was demonstrated in *Ascotis selenaria cretacea* where decapitation resulted in pheromone decline and it could be restored by injecting PBAN (Miyamoto *et al.*, 1999). Decapitation also decreases the epoxide pheromone titer in the gypsy moth, *L. dispar*, and injection of PBAN can restore pheromone production (Thyagaraja and Raina, 1994). However, decapitation did not decrease the levels of the hydrocarbon precursor in the gypsy moth (Jurenka, unpublished data). These findings indicate that PBAN may regulate the epoxidation step in those moths that utilize epoxide pheromones but not the production of the alkene precursor or alkene pheromones.

3.14.5.2.5. Mediators and inhibitors of PBAN action Juvenile hormones play an important role in reproductive development of many moth species (see **Chapters 3.7** and **3.9**). Although JH probably does not regulate pheromone biosynthesis directly it has been shown to be involved in the release of PBAN in the migratory moths *Pseudaletia unipuncta* and *A. ipsilon* (Cusson and McNeil, 1989; Gadenne, 1993; Cusson *et al.*, 1994; Picimbon *et al.*, 1995). In addition, JH has been shown to prime the pheromone glands in pharate adults of the nonmigratory moth *H. armigera* (Fan *et al.*, 1999). JH II, in an *in vitro* assay, primed pheromone glands of pharate adults to respond to PBAN and induced earlier pheromone production by intact newly emerged females (Fan *et al.*, 1999). This induction could be mediated by JH upregulation of a putative PBAN receptor in pharate adults (Rafaeli *et al.*, 2003).

The corpus bursae has been implicated in the mediation of PBAN stimulation of pheromone biosynthesis in some tortricids (Jurenka *et al.*, 1991c). A peptide was partially purified from corpus bursae that could stimulate pheromone production (Fabriàs *et al.*, 1992). To date a bursal factor has only been demonstrated in *A. velutinana* and the related tortricids *C. fumiferana* and *C. rosaceana* (Delisle *et al.*, 1999).

The role of the nervous system in pheromone biosynthesis in moths is not clearly understood. In several moths including *L. dispar* (Tang *et al.*, 1987; Thyagaraja and Raina, 1994), *H. virescens* (Christensen *et al.*, 1991), *S. littoralis* (Marco *et al.*, 1996), and *M. brassicae* (Iglesias *et al.*, 1998) an intact VNC was reported as necessary for pheromone biosynthesis. Christensen and coworkers (Christensen *et al.*, 1991, 1992, 1994; Christensen and Hildebrand, 1995) proposed that the neurotransmitter octopamine might be involved as an intermediate messenger during the stimulation of sex pheromone production in *H. virescens*. These workers suggested that octopamine was involved in the regulation of pheromone production and that PBAN's role lies in the stimulation of octopamine release at nerve endings. However, contradicting results concerning VNC transection and octopamine-stimulated pheromone production were reported in the same species as well as in other moth species (Jurenka *et al.*, 1991c; Ramaswamy *et al.*, 1995; Rafaeli and Gileadi, 1996; Park and Ramaswamy, 1998; Delisle *et al.*, 1999). A modulatory role for octopamine was suggested by research conducted on *H. armigera* (Rafaeli and Gileadi, 1995b; Rafaeli *et al.*, 1997a, 1999). Octopamine and several octopaminergic analogs inhibited pheromone production in studies using both *in vitro* and *in vivo* bioassays in two species of moths (Rafaeli and Gileadi, 1995b, 1996; Rafaeli *et al.*, 1997, 1999; Hirashima *et al.*, 2001). The role of the VNC in pheromone production still requires clarification. It has been suggested, that in some moth species (*S. littoralis*) both humoral and neural regulation occurs (Marco *et al.*, 1996). Given the diversity of moths it may not be surprising to find several mechanisms regulating pheromone biosynthesis.

3.14.5.3. JH Regulation in Beetles

3.14.5.3.1. General In the Coleoptera, pheromone production or release is controlled by JH III (review: Tillman *et al.*, 1999). JH, or JH analogs, stimulate pheromone production in *T. molitor* (Menon, 1970), *T. castaneum* (both Tenebrionidae), some members of the Cucujidae (review: Plarre and Vanderwel, 1999), *A. grandis* (Curculionidae) (Wiygul *et al.*, 1990), and various Scolytidae (see Section 3.14.5.3.2). Various factors may work upstream as cues to stimulate JH biosynthesis. Feeding stimulates pheromone production or release in many species (Vanderwel and Oehlschlager, 1987). Sexual maturity and population density may also be important, e.g., for some Scolytidae (Byers, 1983) and Cucujidae (Plarre and Vanderwel, 1999). The effect of population density may be mediated by sensitivity to pheromone concentrations. Antennectomy can raise pheromone biosynthetic rates in *A. grandis* (Dickens *et al.*, 1988) and *L. decemlineata* (Dickens *et al.*, 2002), suggesting that detection of pheromone components may inhibit their production. Various combinations of physiological and

environmental factors therefore regulate JH titers, which in turn stimulate pheromone biosynthesis and/or release.

3.14.5.3.2. JH regulation in bark beetles (Scolytidae) Aggregation pheromone biosynthesis in bark beetles generally begins shortly after the beetle arrives at a new host tree (Wood, 1982; Seybold *et al*., 2000). Unfed beetles can be artificially stimulated to produce pheromones by treatment with JH III. For example, males are the pioneers of *Ips* spp., and starved male *I. paraconfusus* and *I. pini* can be induced to synthesize the pheromone components ipsenol and ipsdienol if JH III or a JH analog is applied topically (Bordon *et al*., 1969; Chen *et al*., 1988; Ivarsson and Birgersson, 1995; Tillman *et al*., 1998). Similarly, starved *Dendroctonus* spp. can be induced to synthesize pheromone components following treatment with JH (Bridges, 1982; Conn *et al*., 1984). Feeding apparently stimulates the synthesis of JH III in the CA (Tillman *et al*., 1998), resulting in elevated JH titers that trigger pheromone biosynthesis in midgut cells (Hall *et al*., 2002a, 2002b).

Pheromone biosynthesis requires a shift in metabolic priorities, particularly for those beetles that produce large quantities of pheromone. JH must actuate this shift, and since pheromone components are synthesized *de novo* (Seybold *et al*., 1995b), induction of the pheromone biosynthetic pathway involves elevated expression of at least some related genes. This was first demonstrated in *I. paraconfusus*, where JH-treated male beetles have increased HMG-R mRNA levels compared to controls (Tittiger *et al*., 1999). Male *I. pini* and *D. jeffreyi* HMG-R mRNA levels also rise in response to topical JH III applications (**Figure 11**) (Tittiger *et al*., 2003; Tillman, Lu, Tittiger, Blomquist, and Seybold, unpublished data). In all species studied, the response is dose and time dependent and correlates with pheromone component biosynthesis. This is consistent with the hypothesis that JH controls HMG-R, which functions as a regulator of the mevalonate (pheromone biosynthetic) pathway. HMG-S mRNA levels in male *D. jeffreyi* also respond to topical JH applications similarly to HMG-R, though at a more modest level (**Figure 11**) (Tittiger *et al*., 2000). In *I. pini*, mRNA for a GPPS gene is also elevated in JH III-treated beetles (Gilg-Young, Welch, Tittiger, and Blomquist, unpublished data). This enzyme diverts carbon from the normal mevalonate pathway into the pheromone biosynthetic pathway, and is thus also a likely regulatory step.

The HMG-S and HMG-R studies in *D. jeffreyi* show how putative regulatory enzymes are

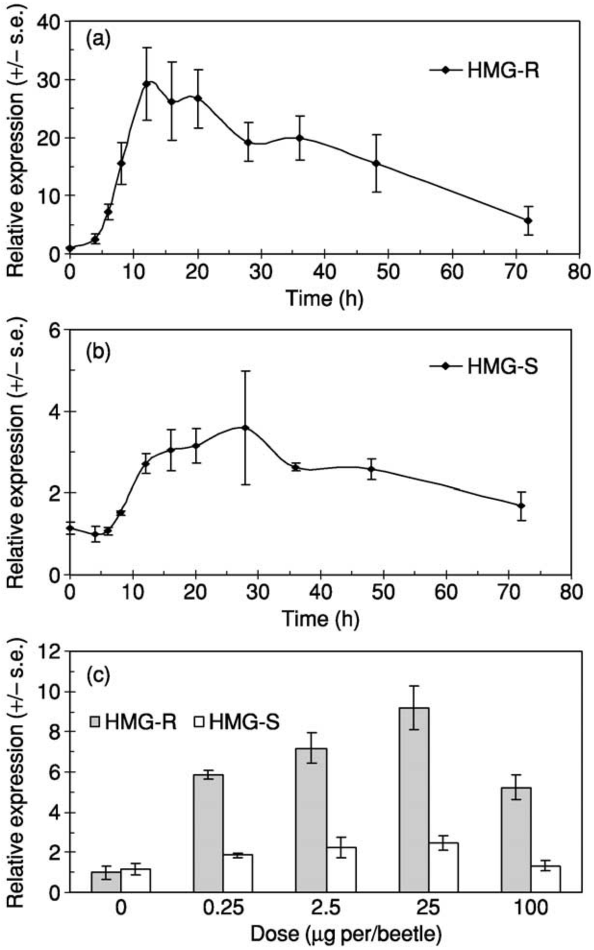

Figure 11 Regulation of *HMG-R* and *HMG-S* expression in male *Dendroctonus jeffreyi* by JH III. The time course (a, b) and dose response (c) for each gene in mature (emerged) males was investigated by Northern blotting. All values are relative to starved, untreated males. Each point represents the mean +/− standard error of three replicates, five isolated thoraces/sample. (Reprinted with permission from Tittiger, C., Barkawi, L.S., Bengoa, C.S., Blomquist, G.J., Seybold, S.J., **2003**. Structure and juvenile hormone-mediated regulation of the HMG-CoA reductase gene from the Jeffrey pine beetle, *Dendroctonus jeffreyi*. *Mol. Cell. Endocrinol.* *199*, 11–21; © Elsevier.)

controlled at the transcriptional level by JH III (though posttranscriptional regulation is probably also important; see below). Their coordinate induction implies that other mevalonate/pheromone biosynthetic genes may also be stimulated by JH III. This question has been addressed mostly in *I. pini*; indeed, more is known about pheromone biosynthetic gene regulation in this insect than in any other beetle, due in part to microarray-based expression profiling. Microarray analyses of male and female JH-treated and untreated *I. pini* give an idea of the profound change that male midgut cells undergo in order to synthesize pheromone, with numerous genes being upregulated or downregulated

following JH III treatment (Keeling and Tittiger, unpublished data). All identified mevalonate pathway genes in a recent expressed sequence tags (ESTs) project (BeetleBase, 2003; Eigenheer *et al.*, 2003) have elevated expression levels compared to controls (Keeling, Bearfield, Blomquist, and Tittiger, unpublished data). These include enzymes at predicted control points (HMG-R and GPPS) as well as others that would not be expected to have a strong regulatory role (e.g., isopentenyl diphosphate (IPP) isomerase). Thus, induction of identified pheromone-biosynthetic genes is apparently coordinate. By extension, genes encoding unidentified enzymes in the pheromone biosynthetic pathway are also likely JH regulated. The putative pheromone precursor, ipsdienone, was recovered from thoracic sections of JH-treated *I. paraconfusus* (Ivarsson *et al.*, 1998), and a male-specific myrcene synthase activity is also elevated in tissues of JH III-treated *I. pini* (Martin *et al.*, 2003). These data provide biochemical evidence that JH III affects enzyme activities converting geranyl diphosphate to ipsdienol, with myrcene and ipsdienone as probable intermediates. Confirmation that the corresponding genes are also JH regulated awaits their identification, and characterization of the relevant enzymes.

In the studies mentioned above, the amount of JH III penetrating the cuticle and acting on the midguts is unknown. A more biologically relevant question is whether feeding similarly stimulates pheromone biosynthetic gene expression. Recent real-time polymerase chain reaction (PCR) studies of RNA recovered from midguts from fed male and female *I. pini* confirm that HMG-R and HMG-S are induced in both sexes by feeding to levels similar to those observed in JH III-treated insects (Keeling and Tittiger, unpublished data). This is curious, because female midguts do not synthesize monoterpenoid pheromones, and female JH III titers do not naturally rise upon feeding (Tillman *et al.*, 1998). Other factors therefore must cause elevated *HMG-R* and *HMG-S* expression in female midguts. These experiments underscore the complexity of gene regulation in bark beetles, and remind us that mevalonate pathway genes almost certainly respond to other, possibly nonpheromone-related factors. Whatever the case, feeding clearly induces expression of certain genes in both male and female tissues, with males having an additional response characterized by increased rates of pheromone biosynthesis.

Juvenile hormone may act as a both trigger and stimulus for pheromone production. The basal HMG-R and HMG-S mRNA levels are from fivefold to eightfold higher in the midguts of males than of females, implying a greater capacity of mevalonate pathway flux in male cells compared to female cells (Keeling and Tittiger, unpublished data). Also, female GPPS mRNA levels, which are not clearly induced by feeding in female *I. pini* midguts, are approximately 16-fold lower than those in male midguts, and GPPS is induced by feeding and JH III treatment in males (Gilg-Young, Welch, Keeling, Bearfield, Blomquist, and Tittiger, unpublished data). This suggests that male midguts may be primed for pheromone biosynthesis, possibly due to an earlier, developmental cue, even before JH III triggers the process, and that pioneer beetles are ready to begin pheromone production when they arrive at a host tree. Subsequent feeding-induced JH III production thus both activates existing components of the pathway and stimulates continued production of pheromone pathway enzymes. Such priming might avoid a potentially dangerous "waiting" period, during which the pheromone-biosynthetic pathway is being stimulated, which would delay the arrival of other beetles to assist colonizing the host tree.

JH appears to be necessary for pheromone production, but it is not always sufficient. Similar gene responses to topically applied JH in male and female *I. pini* belie very different metabolic responses (Tillman, Lu, Seybold, Keeling, Bearfield, Blomquist, and Tittiger, unpublished data), suggesting a control mechanism for *I. pini* that is more complex than having JH III simply stimulate expression of pheromone biosynthetic genes. Other factors may be involved. For example, while all mevalonate pathway genes are induced in male *I. pini*, only genes corresponding to early steps (e.g., thiolase, HMG-R, HMG-S, IPP isomerase) are induced by JH III in females, while those for latter steps (GPPS, farnesyl diphosphate synthase (FPPS)) are not (Keeling *et al.*, 2004). Similarly, JH is clearly not sufficient to stimulate pheromone production in *I. paraconfusus* (Tillman, Lu, Tittiger, Blomquist, and Seybold, unpublished data). JH III-treated male *I. paraconfusus* have elevated HMG-R mRNA levels (the expression of other genes has not been studied in this insect), but neither HMG-R enzyme activity nor monoterpenoid pheromone component levels are significantly increased compared to controls. In contrast, male *I. paraconfusus* that have been allowed to feed on pine phloem have elevated HMG-R activity and, of course, elevated pheromone component levels. Decapitation studies confirm that an unknown ancillary hormone(s) is required in addition to JH III for pheromone biosynthesis (Lu, Blomquist, and Seybold, unpublished data). Presumably, one effect of this factor is in regulating the posttranscriptional activation of

HMG-R. Posttranscriptional regulation of pheromone biosynthetic activity has been demonstrated in other insect systems (e.g., PBAN-regulated activity of bombykol in silkmoths) (Moto *et al.*, 2003), and multilevel control of HMG-R activity is well documented (review: Hampton *et al.*, 1996). Future studies that concentrate on the effects of JH III on protein levels and enzyme activities should provide exciting new information of how JH III regulates the pheromone-biosynthetic machinery in bark beetles.

3.14.5.4. 20-Hydroxyecdysone Regulation of Pheromone Production in the Housefly

3.14.5.4.1. Ecdysteroid regulation Newly emerged female houseflies do not have detectable amounts of any C_{23} sex pheromone components. Sex pheromone production correlates with ovarian development and vitellogenesis. The C_{23} sex pheromone components first appear when ovaries mature to the early vitellogenic stages (Figure 12) and increase in amount until stages 9 and 10 (mature egg) (Dillwith *et al.*, 1983; Mpuru *et al.*, 2001). Females

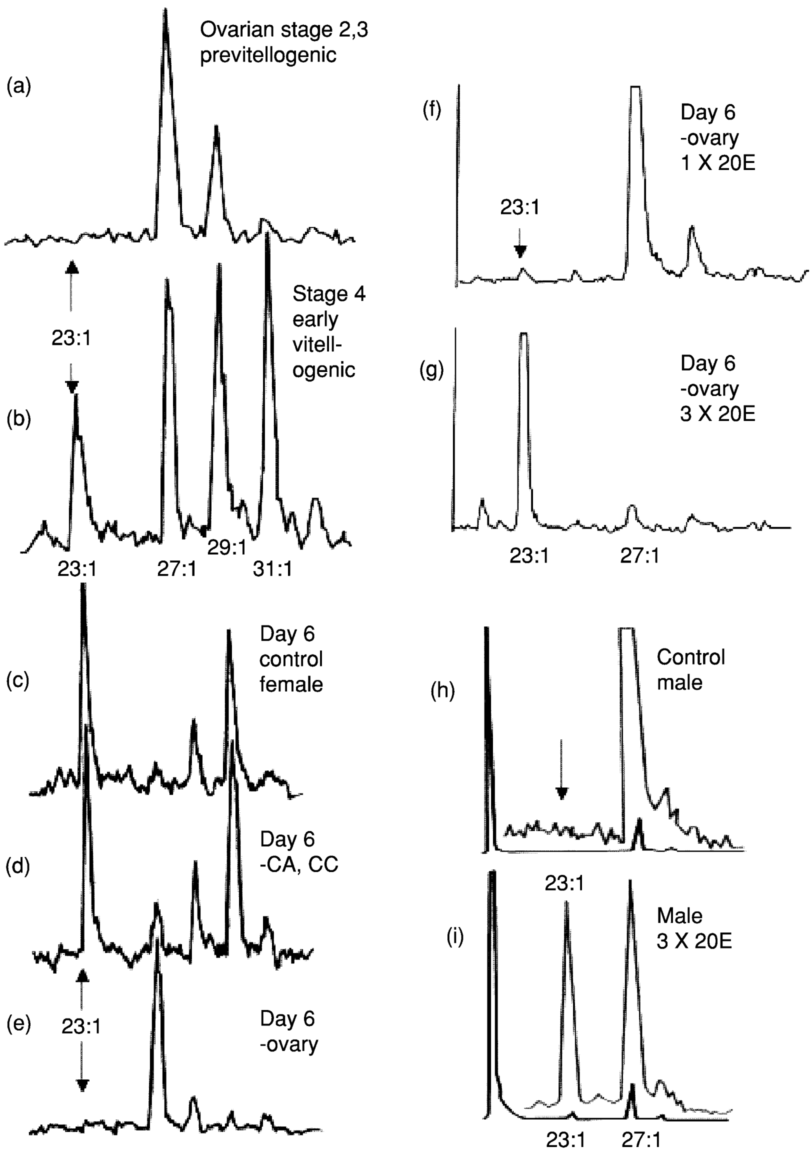

Figure 12 Effect of ovarian development (a, b), ovariectomy and allatectomy (c, d, e), and treatment with 20-hydroxyecdysone (20E) on ovariectomized females (f, g) and males (h, i) on (*Z*)-9-tricosene production. The results show that ovariectomy abolishes pheromone production, whereas treatment with 20E induces pheromone production in ovariectomized females and in males. (Reprinted with permission from Blomquist, G.J., **2003**. Biosynthesis and ecdysteroid regulation of housefly sex pheromone production. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Elsevier, New York, pp. 131–252; © Elsevier.)

ovariectomized within 6 h of adult emergence do not produce any of the C_{23} sex pheromone components, whereas control and allatectomized females produced abundant amounts of (*Z*)-9-tricosene (**Figure 12c–e**). Ovariectomized insects that received ovary implants produced sex pheromone components in direct proportion to ovarian maturation. These data demonstrate that a hormone from the maturing ovary induced sex pheromone production (Blomquist *et al*., 1993, 1998).

Juvenile hormone regulates both vitellogenesis and pheromone production in some insect species (Tillman *et al*., 1999). In some Diptera, including the housefly, ovarian-produced ecdysteroids are involved in regulating vitellogenesis (Hagedorn, 1985; Adams *et al*., 1997) at the transcriptional level (Martin *et al*., 2001). Therefore, since ovariectomy abolished sex pheromone production whereas allatectomy (which abolishes JH production) had no effect on pheromone production (Blomquist *et al*., 1992), it was hypothesized that an ecdysteroid, and not JH, regulated sex pheromone production in the housefly. Injection of 20E at doses as low as 0.5 ng every 6 h induced sex pheromone production in ovariectomized houseflies in a time- and dose-dependent manner (**Figure 12f** and **g**) (Adams *et al*., 1984a, 1984b, 1995). Multiple injections of 20E into ovariectomized insects over several days resulted in as much 23 : 1 produced as in intact control females. Application of JH or JH analogs alone or in combination with ecdysteroids had no effect on pheromone production (Blomquist *et al*., 1992).

3.14.5.4.2. Induction of female sex pheromone production in male houseflies Male houseflies normally produce no detectable C_{23} sex pheromone components, but do produce the same C_{27} and longer alkenes as previtellogenic females. Implantation of ovaries into male houseflies resulted in a change in the chain length specificity of the alkenes such that (*Z*)-9-tricosene became a major component (Blomquist *et al*., 1984a, 1987). Likewise, injection of 20E into males induces sex pheromone production in a dose-dependent manner (**Figure 12h** and **i**). Thus, males possess the biosynthetic capability to produce sex pheromone, but normally do not produce the 20E necessary to induce sex pheromone production. This makes male houseflies a very convenient model to study the regulation of sex pheromone production, circumventing the need to ovariectomize a large number of female insects.

3.14.5.4.3. Ecdysteroids affect fatty acyl-CoA elongation enzymes There are two likely possibilities to account for the change in the chain length of the alkenes synthesized by the female housefly in the production of (*Z*)-9-trecosene. They are: (1) the chain-length specificity of the reductive conversion of acyl-CoAs to alkenes is altered such that 24:1-CoA becomes an efficient substrate, or (2) there is a change in the chain-length specificity of the fatty acyl-CoA elongation enzymes such that 24:1-CoA is not efficiently elongated, resulting in an accumulation of 24:1-CoA. To determine which enzyme activities are affected by 20E to regulate the chain length of the alkenes, experiments were performed to examine the chain-length specificity of the fatty acyl-CoA reductive conversion of acyl-CoAs to alkenes and elongation. Microsomal preparations from both males and females of all ages examined readily converted 24:1-CoA and the 24:1 aldehyde to (*Z*)-9-tricosene, indicating that 20E was not acting on this activity (Tillman-Wall *et al*., 1992; Reed *et al*., 1995). In contrast, microsomes from day-4 females (high ecdysteroid titer and production of (*Z*)-9 tricosene) did not elongate either 18:1-CoA or 24:1-CoA beyond 24 carbons, while microsomes from day-4 males or day-1 females (both of which produce alkenes of 27:1 and longer) readily elongated both 18:1-CoA and 24:1-CoA to 28:1-CoA (Tillman-Wall *et al*., 1992; Blomquist *et al*., 1995). Thus, 20E appears to regulate the fatty acyl-CoA elongases and not the enzymatic steps in the conversion of acyl-CoA to hydrocarbon.

3.14.5.4.4. Transport of pheromone The role of hemolymph in transporting hydrocarbons and hydrocarbon pheromones has only recently become fully appreciated. Older models of hydrocarbon formation showed epidermal-related cells (oenocytes) synthesizing and transporting hydrocarbons directly to the surface of the insect (Hadley, 1984). In the housefly, the role of hemolymph is most clearly seen when (*Z*)-9-tricosene production is initiated. (*Z*)-9-Tricosene first accumulates in the hemolymph, and then, after a number of hours, is observed on the surface of the insect. Modeling of the process (Mpuru *et al*., 2001) showed that the delay is surprisingly long; a period of more than 24 h is necessary for transport from site of synthesis to deposition on the surface of the insect.

In sexually mature females, (*Z*)-9-tricosene comprised a relatively large fraction of the hydrocarbon of the epicuticle and the hemolymph, but much smaller percentages of the hydrocabons in other tissues, including the ovaries. It appears that certain hydrocarbons were selectively partitioned to certain tissues such as the ovaries, from which pheromone was relatively excluded (Schal *et al*., 2001). Both KBr gradient ultracentrifugation and specific

immunoprecipitation showed that over 90% of the hemolymph hydrocarbon was associated with a high-density lipophorin (see **Chapter 4.6**). Lipophorin was composed of two aproproteins under denaturing conditions: apolipophorin I (≈240 kDa) and apolipophorin II (≈85 kDa) (Schal *et al.*, 2001). The data suggest that lipophorin may play an important role in an active mechanism that selectively delivers specific hydrocarbons to specific sites.

3.14.5.5. Regulation of Pheromone Production in Cockroaches

3.14.5.5.1. Development and cellular plasticity of pheromone glands In cockroaches, in striking contrast to many moths, pheromone glands acquire functional competence during an imaginal maturation period, and developmental regulation involves factors that also control adult reproductive readiness. Also, because reproduction in cockroaches is interrupted by periods of sexual inactivity (i.e., gestation), developmental regulation of the sex pheromone gland can result in alternating cycles of acquisition and subsequent waning of competence through maturation and retrogression, respectively, of cellular machinery. Consequently, in female cockroaches pheromone production is controlled by cyclic maturational changes in the gland in relation to the ovarian cycle.

Best exemplifying this phenomenon are the tergal and sternal glands of *N. cinerea* and *B. germanica* males. Both species possess class-3 glandular units, composed of two cells – a secretory cell and a duct cell (Quennedey, 1998). But after apolysis and before the imaginal molt the immature gland contains four concentric cells, including in addition to the two adult cells an enveloping cell and a ciliary cell (Sreng and Quennedey, 1976; Sreng, 1998). During several days after the adult molt the gland matures, in part by undergoing apoptosis (programmed cell death). The ciliary cell gives rise to a part of the microvillar end-apparatus, then dies, whereas the enveloping cell forms an upper portion of the duct, then it too dies (Sreng, 1998). In concert, before day 5 the immature sternal glands of *N. cinerea* males produce little pheromone, but after day 5 their pheromone content increases significantly (Sreng *et al.*, 1999). Decapitation or allatectomy of *N. cinerea* males completely blocked the apoptotic process, while JH III treatment restored apoptosis (Sreng *et al.*, 1999). Brain extracts or synthetic moth PBAN failed to restore gland differentiation or stimulate pheromone production.

Female *B. germanica* employ similar class-3 glands to produce a volatile sex pheromone that is yet to be identified. Ultrastructural, behavioral, and electrophysiological studies have shown that, as in males, pheromone gland cells mature as the female sexually matures (Abed *et al.*, 1993b; Liang and Schal, 1993; Tokro *et al.*, 1993; Schal *et al.*, 1996). The secretory cells of newly formed glands in the imaginal female are small and they contain little pheromone (determined by behavioral and EAG assays). As the female sexually matures, the size of pheromone-secreting cells increases, as does its pheromone content (Liang and Schal, 1993). The mature pheromone gland then undergoes cycles of cellular hypertrophy and retrogression in relation to the JH III titer in successive reproductive cycles. The gland becomes atrophied and its pheromone content declines during gestation, but as a new vitellogenic cycle begins after the egg case is deposited, the pheromone gland undergoes rapid regrowth and proliferation of cellular organelles and an increase in its pheromone content. Although this pattern corresponds well with the JH III titer in the hemolymph (Liang and Schal, 1993; Schal *et al.*, 1996), no experimental manipulations of hormone titers have been conducted to verify the hypothesis that JH III controls the cellular plasticity of the pheromone gland.

3.14.5.5.2. Pheromone production regulated by juvenile hormone Barth and Lester (1973) and Schal and Smith (1990) reviewed the early literature on hormone involvement in pheromone production in cockroaches. With the exception of *Nauphoeta* (detailed above), no studies on the regulation of volatile pheromone production are available that use analytical or biochemical approaches. The most detailed studies, with *B. germanica* and *S. longipalpa*, have employed behavioral and EAG responses of males to estimate the relative amount of pheromone in females or their pheromone glands. In both species, virgin females initiate pheromone production 4 days after the imaginal molt, in relation to increasing titers of JH III (Smith and Schal, 1990a; Liang and Schal, 1993). Ablation of the corpus allatum (CA) of newly emerged adult females prevents pheromone production in both species, and pheromone production is restored after reimplantation of active CA or by treatment with JH III or JH analogs. Interestingly, although growth of the vitellogenic oocytes is controlled by and highly correlated with JH III titers, direct or even intermediary involvement of the ovaries in regulating pheromone production and calling behavior in both species was excluded by ovariectomies (Smith and Schal, 1990a).

It is not known whether JH exerts its pheromonotropic effects directly on mature secretory cells of

the pheromone gland or if it acts indirectly by stimulating the synthesis and/or release of pheromonotropic neuropeptides. Although cockroach brain extracts induce PBAN-like pheromonotropic activity in moth pheromone glands (Raina *et al*., 1989), they fail to do so in allatectomized *Nauphoeta* males (Sreng *et al*., 1999) or *Supella* females (Schal, unpublished data). Moreover, lack of pheromone production in mated females that periodically produce large amounts of JH III suggests that JH plays a "permissive" role (Smith and Schal, 1990b; Schal *et al*., 1996). That is, its presence is required for pheromone to be produced, but even when the JH III titer is high pheromone production can be suppressed by neural or humoral pheromonostatic factors.

Blattella germanica has served as a useful model for delineating endocrine regulation of nonvolatile cuticular pheromones, namely (3*S*,11*S*)-dimethylnonacosan-2-one. Both the amount of pheromone on the cuticular surface and *in vivo* incorporation of radiolabel from [$^{14}C_1$]propionate into the sex pheromone coincide with active stages of vitellogenesis, suggesting the involvement of JH (Schal *et al*., 1990a, 1994; Sevala *et al*., 1999). Indeed, females treated so as to reduce their JH III titer (allatectomy, antiallatal drugs such as precocene, starvation, or implantation of an artificial egg case into the genital vestibulum, which inhibits JH biosynthesis) produce less pheromone (Schal *et al*., 1990a, 1994; Chase *et al*., 1992). Furthermore, pheromone production is greatly stimulated by treatments with JH III or with JH analogs. Because only the hydroxylation of 3,11-dimethylnonacosane to 3,11-dimethylnonacosan-2-ol is regulated in a sex-specific manner, it appears that this step is under JH III control (**Figure 11**) (Chase *et al*., 1992).

Normally, adult male cockroaches have a much lower titer of JH III in the hemolymph (Piulachs *et al*., 1992; review: Wyatt and Davey, 1996). Because males also produce 3,11-dimethylnonacosane, metabolism of the alkane to contact pheromone may be contingent upon high JH titers in the adult female. In response to exposure to the JH analog hydroprene, female pheromone increased sixfold in treated males (Schal, 1988), showing some capacity to express the putative female-specific polysubstrate monooxigenase. The parallels are striking with estrogen induction of vitellogenin synthesis in the male liver of oviparous vertebrates, JH induction of vitellogenin synthesis in male cockroaches (Mundall *et al*., 1983), and ecdysteroid induction of female pheromone production in houseflies (see Section 3.14.5.3.2) (Blomquist *et al*., 1984b, 1987).

Contact pheromone production in *B. germanica* is also regulated through the regulated production of its precursor, 3,11-dimethylnonacosane. Biosynthesis of this alkane drops dramatically when food intake declines at the end of each vitellogenic phase (Schal *et al*., 1994, 1996), suggesting that hydrocarbon biosynthesis is linked to food intake, as in nymphs (Young *et al*., 1999), and not directly to either the ecdysteroid or JH titers. Dietary intake also stimulates the production of JH III (Schal *et al*., 1993; Osorio *et al*., 1998), which in turn stimulates the conversion of the alkane to contact pheromone. In allatectomized females large amounts of hydrocarbons accumulate in the hemolymph because food intake is not suppressed (i.e., no gestation) and hydrocarbons are not provisioned into oocytes (i.e., no vitellogenesis) (Schal *et al*., 1994; Fan *et al*., 2002). As hydrocarbons accumulate in the hemolymph, the amount of cuticular pheromone also increases, suggesting that excess 3,11-dimethylnonacosane is metabolized to pheromone. These patterns suggest that under normal conditions, feeding in adult females is modulated in a stage-specific manner, regulating the amount of 3,11-dimethylnonacosane that is available for JH-mediated metabolism of 3,11-dimethylnonacosane to 3,11-dimethylnonacosan-2-one.

3.14.5.5.3. Transport and emission of pheromones Little is known of the cellular processes that deliver volatile pheromones from secretory cells to the cuticular surface, even in the intensively researched Lepidoptera. In cockroaches, electron microscopy studies often show accumulation of secretion in the end-apparatus, ducts, and around the cuticular pores of class-3 exocrine glands in both males and females. Recent studies in *L. maderae* have identified and sequenced an epicuticular protein, Lma-p54, that is expressed specifically in the tergites and sternites of adult males and females, but not in nymphs (Cornette *et al*., 2002). The sequence of this protein is closely related to aspartic proteases, but because it appears to be enzymatically inactive the authors speculate that it serves as a ligand-binding protein. Cornette *et al*. (2002) further hypothesize that Lma-p54, alone or together with a ligand, serves in sexual recognition. Other ligand-binding proteins, namely the lipocalins Lma-p22 and Lma-p18, have been isolated only from male tergal secretions of *L. maderae* (Cornette *et al*., 2001). These exciting findings suggest that carrier proteins might be involved in the transport of volatile pheromones to the cuticle, but functional studies will be needed to verify this hypothesis.

Attractant sex pheromones are usually emitted while the female or male cockroach performs a species-specific calling behavior (Gemeno and Schal, 2004; Gemeno *et al*., 2003). As in most lepidopterans, JH III regulates calling behavior in both species *B. germanica* and *S. longipalpa*. In both species, transection of the nerves connecting the CA to the brain, an operation that significantly accelerates the rate of JH III biosynthesis by the CA (Schal *et al*., 1993), also hastens the age when calling first occurs (Smith and Schal, 1990a; Liang and Schal, 1994). In *B. germanica*, the central role of JH has been confirmed by ablation of the CA and with rescue experiments with a JH analog (Liang and Schal, 1994). In this species, JH is also required for females to become sexually receptive and accept courting males (Schal and Chiang, 1995).

In *B. germanica*, the transfer of contact pheromones to the epicuticular surface is mediated by lipophorin, a high-density hemolymph lipoprotein (reviews: Schal *et al*., 1998b, 2003). As in *M. domestica* (see Section 3.14.5.4.4), newly biosynthesized pheromone appears first in the hemolymph before it is noted on the epicuticle (Gu *et al*., 1995). That hemolymph is required to transport the pheromone to the cuticular surface was demonstrated by severing the veins that enter the forewings. Subsequently, the amount of hydrocarbons and pheromone that appeared on the wings was significantly lower than on the intact forewings of the same insects.

In the cockroaches *P. americana* and *B. germanica*, virtually all newly synthesized hydrocarbons that enter the hemolymph are bound to lipophorin (Chino, 1985; Gu *et al*., 1995). Moreover, in both species newly synthesized hydrocarbons can only be transferred from the integument to an incubation medium if lipophorin is present, and other hemolymph lipoproteins, such as vitellogenin, cannot mediate this transfer (Katase and Chino, 1982, 1984; Fan *et al*., 2002). The mechanisms by which hydrocarbons and pheromones are taken up by lipophorin are poorly understood. Takeuchi and Chino (1993) demonstrated clearly in the American cockroach that a very-high-density lipid transfer particle (LTP) catalyzes the transfer of hydrocarbons between lipophorin particles. However, *in vitro* experiments with purified lipophorin of *P. americana* and *B. germanica* have shown that lipophorin accepts hydrocarbons from oenocytes, apparently without the involvement of LTP (Katase and Chino, 1982, 1984; Fan *et al*., 2002). It remains to be determined whether this is because sufficient LTP remains bound to dissected tissues, if LTP is produced by the dissected tissues, or whether it plays no significant role in hydrocarbon and pheromone uptake by lipophorin.

Interestingly, while the uptake of hydrocarbons and pheromones by lipophorin *in vitro* appears to lack molecular specificity (Katase and Chino, 1984; Fan and Schal, unpublished data), their delivery to pheromone gland cells is highly specific (Schal *et al*., 1998a, 1998b). Uptake of lipophorin and its ligands might involve receptor-mediated endocytosis, as demonstrated in mosquito oocytes (Cheon *et al*., 2001; see **Chapter 3.9**). This might explain why some 3,11-dimethylnonacosan-2-one has been isolated from mature ovaries of the German cockroach (Gu *et al*., 1995) and (*Z*)-9-tricosene is found in housefly ovaries (Schal *et al*., 2001). However, an endocytic process would fail to discriminate various ligands, suggesting that alternative mechanisms need to be investigated.

3.14.6. Concluding Remarks and Future Directions

Our increased understanding of the biochemistry and regulation of pheromone production over the last two decades has been most impressive. A 1983 review of the biochemistry and endocrine regulation of insect pheromone production (Blomquist and Dillwith, 1983) was 16 pages long. It was limited to early work on pheromone biosynthesis in moths and the housefly, and recognized that JH and ecdysteroids may play a role in the regulation of pheromone production. Since that time the discovery of PBAN and its role in the regulation of lepidopteran pheromone production have been elucidated, along with determining which enzymes are affected by JH and ecdysteroids to regulate pheromone production in model cockroaches/beetles and flies, respectively. The work in Lepidoptera has moved from simply demonstrating that pheromone components were synthesized *de novo* to the molecular characterization of the unique Δ11-desaturase and other desaturases that are involved in many female moths and their interplay with specific chain shortening steps. While it is still true that in no system do we have a complete understanding of both the biochemical pathways and their endocrine regulation, we do have a much better understanding of how pheromones are made and in some systems are developing an understanding of their regulation at the molecular level. The continued application of the powerful tools of molecular biology along with studies using genomics and proteomics will only increase the rate at which we increase our understanding of pheromone production. Ultimately, just as behavioral chemicals themselves have been extended into pest

control, research on pheromone production will be directed toward practical applications in insect control.

3.15 Molecular Basis of Pheromone Detection in Insects

R G Vogt, University of South Carolina, Columbia, SC, USA

3.15.1. Introduction

The detection of environmental chemicals is surely one of the oldest senses, critical to bacteria, single-celled eukaryotes, plants, fungi, and animals. Chemical signatures carry enormously diverse information about the external world. Pheromones represent one class of environmental signals and are stringently defined as chemicals produced by individuals and detected by other members of the same species (Karlson and Lüscher, 1959). Pheromones have been categorized as primers, stimulating or modulating an immediate behavioral response, and releasers, stimulating or modulating a longer-lasting physiological state (Birch, 1974; Wyatt, 2003).

Pheromone detection is viewed as among the most specialized form of chemodetection, and the mechanisms underlying the detection and processing of pheromone signals have been viewed not merely as a comprising a special case of chemodetection, but often as a distinct process. However, chemicals produced outside the species may have effects as profound as pheromones on an individual, either short term or long term. Furthermore, the underlying mechanisms for detecting and processing pheromone and nonpheromone chemical signals are turning out to be quite similar (e.g., Christensen and Hildebrand, 2002). Certain chemical signals, including pheromones but also karimones (signals between species) and plant-derived oviposition cues, are components of processes that have special roles in the life of an organism, and as such, evolutionary selection has acted to elaborate preexisting detection/response pathways in ways appropriate for the processing of those chemical signals. So, while pheromone detection pathways are clearly under different kinds of selective pressure than say food-odor detection pathways, the specializations seen in pheromone pathways are most likely modifications of an overall common process. Nevertheless, pheromones are clearly unique among all chemical signals, in that selection has acted on different members of the same species to coordinate both the production and detection of these signals. And yet, remarkably much is still unexplored in the area of the physiological/hormonal regulation of these two distinct pheromonal processes.

How are pheromones detected? Insects have two major chemosensory systems, olfaction (smell) and gustation (taste) (Stocker, 1994). Pheromones might be detected by either system, though virtually all that is known about the mechanisms underlying pheromone detection involves olfaction.

Olfaction might be defined as the detection of volatile chemostimulants, but a more appropriate definition relates to the unique neuroanatomy of olfaction. In insects, odors are detected by olfactory sensilla which come in a variety of shapes, including long and short hair-like structures and plate-like

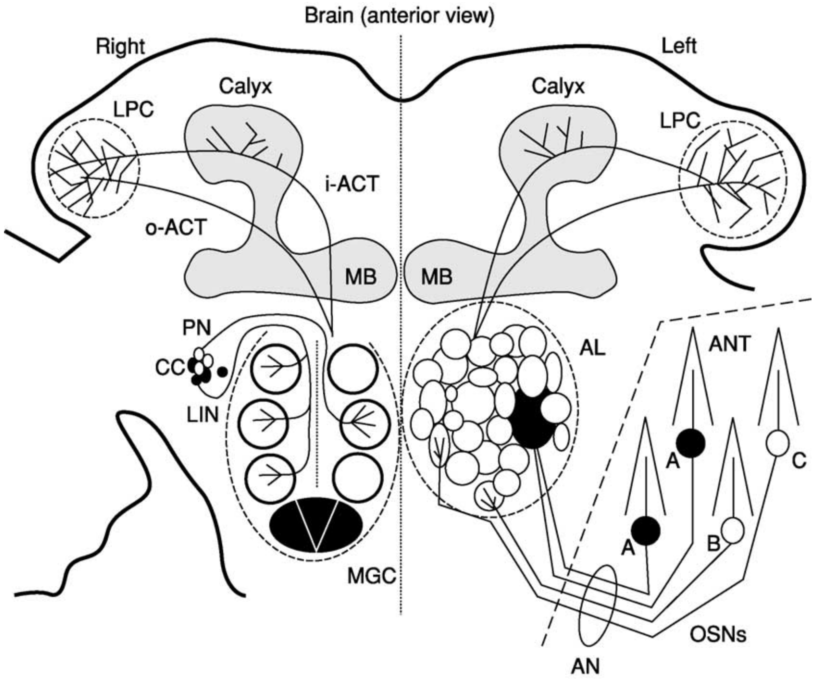

Figure 1 Frontal view of an adult insect brain detailing olfactory pathways through the brain. Left: Dendrites and cell bodies of olfactory sensory neurons (OSNs) are located in the antennas (ANT) and palps within sensilla; axons project, via the antennal nerve (AN), to spherical glomerulae in the antennal lobe (AL) where they synapse with local interneurons (LINs) and projection neurons (PNs). OSNs expressing the same OR project to the same glomerulus (e.g., neurons A) while OSNs expressing different receptors project to different glomerulae (e.g., neurons B, C) (Hansson *et al.*, 1992, 2003; Anton and Hansson, 1995; Joerges *et al.*, 1997; Galizia *et al.*, 1998, 1999, 2000; Gao *et al.*, 2000; Vosshall *et al.*, 2000; Galizia and Menzel, 2001; Carlsson *et al.*, 2002; Sadek *et al.*, 2002; Marin *et al.*, 2002; Carlsson and Hansson, 2003a, 2003b). Right: The AL contains multiple types of glomerulae, including specialized glomerulae such as the macroglomerular complex (MGC) (male specific in Lepidoptera) which comprises several glomerular units each receiving input from OSNs responding to specific components of a sex-pheromone blend (e.g., Christensen and Hildebrand, 2002; Hansson, 2002). LINs and PNs project from cell bodies located in one of several cell clusters (CC) located just outside the glomerular mass. LINs are multiglomerular, innervating all glomerulae, only the non-MGC glomerulae, or only the MGC (Matsumoto and Hildebrand, 1981; Hansson *et al.*, 1994). PNs are uniglomerular and projecting outward to the lateral protocerebrum (LPC) via one of two tracks. PNs of the inner antenno-cerebral tract (i-ACT) make synaptic connections with neurons of the mushroom bodies (MB) as well as in the LPC, while PNs of the outer antenno-cerebral tract (o-ACT) only make synaptic connections in the LPC (Homberg *et al.*, 1988; Kanzaki *et al.*, 1989, 2003; Hansson *et al.*, 1991; Sun *et al.*, 1997; McGuire *et al.*, 2001). Individual PNs innervate spatially restricted regions of the LPC, suggesting that there is a spatial conservation between glomerulus and LPC domain (Wong *et al.*, 2002).

structures, and which may have single or double cuticular walls; but all are multiporous, having many small holes penetrating the cuticle to provide odor molecules access to chemosensory neurons within (Steinbrecht, 1997, 1999; Boeckh *et al.*, 1965; see also Schneider, 1969; Kaissling, 1971). Adult olfactory neurons project to the olfactory lobes in the brain (Hildebrand, 1996; Hansson *et al.*, 2003) (**Figure 1**); larval olfactory neurons project to a location in the brain homologous to the adult olfactory lobe (Kent and Hildebrand, 1987; Python and Stocker, 2002). The dendrites of olfactory neurons are ensheathed within cuticular hairs, comprising olfactory sensilla which are restricted to the head (primarily antennas and maxillary palps) (Steinbrecht, 1997, 1999). While these olfactory sensilla certainly detect volatile chemicals for terrestrial insects, there are no data to say that homologous structures, as opposed to contact or gustatory sensilla, do not detect water-soluble molecules for aquatic insects. Nevertheless, it is the axonal projection pathway of the chemsensory neurons to the olfactory lobe that most consistently distinguishes the olfactory from the gustatory system.

Gustation might be defined as the detection of nonvolatile chemostimulants, but again, an anatomically based definition may better serve. Gustatory sensilla have a single pore at the tip (Steinbrecht, 1984); their frequent description as contact chemoreceptors confers the idea that these sensilla must make physical contact with a substrate permitting a chemostimulant to flow into the pore and to the sensory neurons within. Gustatory sensilla typically contain several chemosensory neurons tuned to

various modalities which may include nutrients, feeding stimulants or deterrents, water and/or salts, and may also include a mechanosensitive neuron (Hanson and Dethier, 1973; Steinbrecht, 1984; Kent and Hildebrand, 1987; Singh, 1997; Shanbhag *et al.*, 2001b). Neurons of these sensilla located on the head project to the subesophageal ganglia (Kent and Hildebrand, 1987; Dunipace *et al.*, 2001; Scott *et al.*, 2001). Gustatory sensilla are also situated elsewhere on the insect body, including legs, wings, and genitalia, and chemosensory axons from these locations project to the appropriate ganglion or ganglionic region serving that segment (Stocker, 1994). In general, neurons of gustatory sensilla do not project to the olfactory lobe, again providing a distinction between these two systems. However, a very small number of the gustatory receptor genes recently identified in *Drosophila melanogaster* have been shown to express in neurons that do project to the olfactory lobe (Scott *et al.*, 2001), emphasizing, perhaps, that in biology, no human-made distinctions should be set in stone.

There seems no reason that insect pheromones should be detected exclusively by olfactory rather than gustatory sensilla, although the majority of those pheromones that have been characterized are processed by the olfactory system. Nevertheless, pheromones run the gamut of volatility, including the relatively nonvolatile cuticular hydrocarbon pheromones of dipteran and various social insects (Blomquist *et al.*, 1998; Blomquist, 2003) (see **Chapter 3.14**). Also, there are numerous examples of insect courtship that employ both pheromones of low volatility and physical contact, suggesting that physical contact may be required for pheromone transfer, e.g. orthopteroids (Tregenza and Wedell, 1997; Rivault *et al.*, 1998) and social insects (review: Clement and Bagneres, 1998). *Drosophila* employs several types of pheromones. Several peptides are transferred with the spermatophore during mating which may enter the hemolymph and bind to olfactory axons to modulate olfactory response (Ottiger *et al.*, 2000) (see **Chapter 1.5**). A volatile aggregation pheromone, *cis*-vaccenyl acetate, is deposited on eggs and detected by trichoid sensilla on the antennas (Bartelt *et al.*, 1985; Clyne *et al.*, 1997). Various cuticular hydrocarbons also influence courtship behavior, including female specific *cis,cis*-7,11-heptacosadiene which alters male wing-beat frequency, and others which inhibit male–male interaction (Ferveur *et al.*, 1996, 1997; Ferveur, 1997; Savarit *et al.*, 1999).

The *Drosophila* cuticular hydrocarbon pheromones have been assumed to be detected by contact gustatory sensilla (Greenspan and Ferveur, 2000). In particular, *Drosophila* prothoracic legs show a sexual dimorphism in the number of gustatory sensilla, with males having the greater number (Nayak and Singh, 1983; Meunier *et al.*, 2000). This sexual asymmetry in sensilla number has led to suggestions that these sensilla may contain neurons that respond to the cuticular hydrocarbon pheromones (Robertson, 1983; Venard *et al.*, 1989; Stocker, 1994; de Bruyne, 2003). These sensilla have yet to be evaluated for the physiological response to cuticular hydrocarbons. However, they have been shown to respond to sugars, salts, and amino acids (the expected stimulants of the respective chemosensory neurons) and furthermore to show a corresponding sexual asymmetry in their response to these nonpheromonal stimulants (Meunier *et al.*, 2000), suggesting some sex-specific but nonpheromonal role for these gustatory sensilla. It may yet be demonstrated that *Drosophila* gustatory sensilla detect pheromones, but so far only olfactory sensilla of the antenna have been shown to participate in courtship behavior (Stocker and Gendre, 1989) or pheromone detection (Bartelt *et al.*, 1985; Clyne *et al.*, 1997). (Note: since this chapter was submitted, new data have been presented suggesting *Drosophila* leg gustatory sensilla are involved in pheromone detection, mediated by gustatory receptor gene Gr68a; see Bray and Amrein, 2003; Matsunami and Amrein, 2003.)

It remains less than definitive that any insect pheromones are in fact detected by gustatory sensilla. However, gustatory sensilla have been shown to function as pheromone detectors in noninsect arthropods such as ticks (Sonenshine, 1985; de Bruyne and Guerin, 1998). The lack of information from insects may merely be a sampling bias, with the vast majority of molecular and physiological research effort being focused on relatively few types of olfactory based pheromones.

This review covers the molecular biology of insect olfaction and to a lesser extent taste, with specific attention to those biochemical events, which led to the initial depolarization of chemosensory neurons. The discussion will be restricted to known gene products and the processes they mediate. In most cases, there are excellent examples of these processes working in the detection of pheromones. The exception to this is with odor receptors; as of early 2000s no pheromone receptor proteins have been reported, though this circumstance will likely change by the time this work is published, or very soon thereafter, as the genomes of the honeybee and several Lepidoptera become fully characterized.

3.15.2. Molecular Basis of Insect Chemodetection: General Schemes

Figure 2 summarizes our current general understanding of the biochemical events involved in the detection of pheromones and other odors by insect olfactory sensilla. Odor molecules enter the aqueous lumen of a sensillum via pores penetrating the cuticle (Steinbrecht, 1997; Steinbrecht and Stankiewicz, 1999). Once inside, odors are thought to bind to and be transported by soluble odorant binding proteins (OBPs) which deliver the odors to transmembrane olfactory receptor proteins (ORs). Odor molecules are subsequently degraded by a variety of enzymes that may be located within the sensillum lumen as well as within the cells lining the base of the sensillum. ORs so far identified are 7-transmembrane domain G-protein-coupled receptors (Vosshall and Keller, 2003); activation of these receptors is thought to generate a rapid increase in inositol triphosphate (IP3) which is thought to directly activate ion channels in the neuronal membrane. The *Drosophila* genome contains at least 61 OR genes and more than 50 OBP genes, providing the molecular basis for the detection of diverse odorants. For all but the ORs and arrestins, each of the biochemical events depicted in Figure 2 has examples in the processing of pheromone signals.

The biochemical processes at work in gustatory sensilla are less well characterized. Gustatory sensilla generally contain multiple sensory neurons including several chemosensory neurons and often one mechanosensory neuron; the chemosensory neurons are tuned to different modalities allowing insects, as is the case with vertebrates, to distinguish sweet, sour, salty, and bitter substances (review: Singh, 1997). However, the range of chemicals that insects detect with these sensilla is likely quite broad, e.g., ecdysteroid chemodetection (Descoins and Marion-Poll, 1999). A family of at least 55 G-protein coupled gustatory receptor (GR) genes has recently been identified in *Drosophila* (Clyne *et al*., 2000; Dunipace *et al*., 2001; Scott *et al*., 2001) and the malaria mosquito *Anopheles gambiae* (Hill *et al*., 2002). Of these, one (Gr5a) has been shown to interact with the sugar trehalose (Dahanukar *et al*., 2001; Ueno *et al*., 2001). An IP3 cascade, similar to that shown in Figure 2c, has also been described for the gustatory detection of sugars and amino acids (Koganezawa and Shimada, 2002). A member of the OBP family has also been reported to associate with certain gustatory sensilla of the blowfly *Phormia regina*, but participates in the detection of certain volatile compounds rather than those (e.g., sugars and amino acids) typically associated with gustatory sensilla (Ozaki *et al*., 1995, 2003).

The term "perireceptor events" was coined by Getchell *et al*. (1984) to describe processes in vertebrate olfaction that preceded the odor–OR interactions (see also Carr *et al*., 1990). The equivalent events in insect olfaction are depicted in Figure 2b, and are those involving OBPs, ODEs, and their interaction with ORs. Transductory events, then, are those depicted in Figure 2c, and involve ORs and the second messenger pathway(s) they regulate. While these two processes, perireception and transduction, clearly overlap at least at the level of the ORs, they remain useful distinctions. In particular, the transduction events that follow receptor activation appear relatively common for all odor–OR combinations. There may be more than one transduction pathway involved, as has been observed in the lobster (*Panulirus argus*) where both IP3 and cAMP pathways exist (Fadool and Ache, 1992; Michel and Ache, 1992; Boekhoff *et al*., 1994; Hatt and Ache, 1994). However, the immediate transduction elements (Figure 2c) do not show the genetic diversity seen for the perireceptor elements (Figure 2b). The OBPs, ODEs, and ORs are present in numbers and diverse sequences or types that suggest they are under strong evolutionary selective/diversification pressures characteristic of both the broad chemoreceptive needs and the divergent life histories of the species.

The majority of the elements depicted in Figure 2 have been identified since the publication of the previous edition of this work. In the early 1980s there were few laboratories studying the biochemistry of odor detection in insects. In 1981 the first identification of a pheromone binding protein (PBP) and a sensillar esterase (SE) was reported; both appeared uniquely expressed in the male antennas of the silk moth *Antheraea polyphemus* and were present in the extracellular fluid of the sensillum lumen (Vogt and Riddiford, 1981). In 1985 a scheme was proposed in which pheromone molecules first bound to PBPs for transport to ORs and were subsequently rapidly degraded by SEs (Vogt *et al*., 1985). The perceived need for such transport arose because pheromone molecules are hydrophobic odors that should not readily enter the aqueous interior of the sensillum lumen. This new scheme was a dramatic departure from the prevailing view that pore tubules (anatomical structures of the cuticle wall) served as conduits for odors from air to neuron (reviews: Vogt, 1987; Steinbrecht, 1997). The subsequent identification of general odorant binding proteins (GOBP1 and GOBP2) suggested that this new scheme might be extended to other

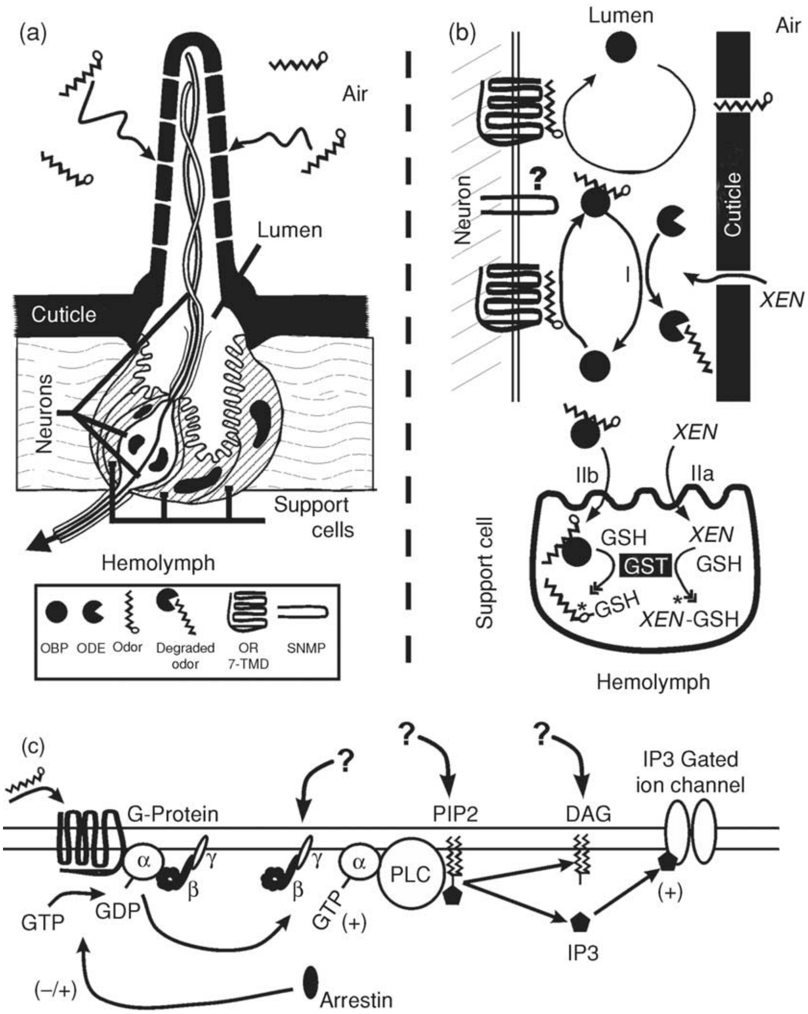

Figure 2 Schematic of an olfactory sensillum and a generalized biochemical pathway of odor reception. (a) Anatomy. An olfactory sensillum includes two or three neurons surrounded by three support cells; olfactory dendrites/cilia project up the fluid-filled lumen of a cuticular hair. The sensillum lumen is isolated from hemolymph by a cellular barrier. (Modified from Steinbrecht, R.A., **1969**. Comparative morphology of olfactory receptor. In: Pfaffmann, C. (Ed.), Olfaction and Taste III. Rockefeller University Press, New York, pp. 3–21.) Olfactory sensilla come in a range of shapes, including plate-like and long and short hair-like structures, and olfactory neurons may have branched or unbranched dendrites; sensilla classes are in part defined by the shape of the cuticular hair and the branched nature of the neurons (Steinbrecht, 1997, 1999). There are little data on the functional differences between different sensilla classes of a given individual, although in Lepidoptera, attractant sex pheromones are detected by the long trichoid sensilla, illustrated here. (b) Perireceptor events. Hydrophobic odor molecules enter the aqueous sensillum lumen via pores penetrating the cuticular hair wall. Hydrophilic odorant binding proteins (OBPs) are proposed to bind and transport odors to receptor proteins located in the neuronal membranes. Odor degrading enzymes (ODEs) (pathway I) in the sensillum lumen are proposed to degrade these odor molecules. Cytoplasm of support cells contains xenobiotic inactivating enzymes (pathway IIa), such as glutathione-*S*-transferase (GST), which may also serve to inactivate odor molecules (pathway IIb). Interactions between OBPs and ORs and the function of sensory neuron membrane proteins (SNMPs) are unclear. (Modified from Rogers, M.E., Jani, M.K., Vogt, R.G., **1999**. An olfactory specific glutathione *S*-transferase in the sphinx moth *Manduca sexta*. *J. Exp. Biol. 202*, 1625–1637.) (c) Transduction events. Odor–OR interaction stimulates an inositor triphosphate (IP3) second messenger cascade in which the α-subunit of a G-protein activates phospholipase C (PLC) to cleave the membrane lipid phosphotidyl inositol 4,5-bisphosphate (PIP2) to diacylglycerol (DAG) and IP3. IP3 is thought to bind directly to and activate transmembrane cation channels (IP3 receptors) (review: Krieger and Breer, 2003). Processes such as those mediated by phosphorylation (Schleicher *et al.*, 1994) or arrestins (Merrill *et al.*, 2002) may provide modulatory feedback on receptor–G-protein interactions. ‘‘?’’ pointing to Gβγ, PIP2, and DAG are to imply yet uncharacterized but possible modulatory roles for these signals.

olfactory modalities such as the detection of plant volatiles (Vogt and Lerner, 1989; Vogt *et al*., 1991a). The identification of an antennal specific but sex indifferent pheromone degrading aldehyde oxidase (AOX) in the moths *Manduca sexta* and *A. polyphemus* suggested that ODEs might also be a general feature of olfaction for both pheromones and plant volatiles (Rybczynski *et al*., 1989, 1990).

Prestwich joined these efforts in the mid-1980s synthesizing valuable chemical probes and pheromone analogs (Prestwich *et al*., 1984; Vogt *et al*., 1985, 1988) and elucidating the pheromone binding properties of PBPs (Prestwich, 1985, 1987; Du *et al*., 1994; Du and Prestwich, 1995; Plettner *et al*., 2000; Lazar *et al*., 2002). Many more laboratories became interested in OBPs beginning in the late 1980s, greatly expanding knowledge of the range of species possessing these proteins and knowledge of the size and diversity of the OBP gene family in single species (reviews: Pelosi and Maida, 1995; Krieger and Breer, 1999; Vogt *et al*., 1999; Leal, 2003; Nagnan-Le Meillour and Jacquin-Joly, 2003; Plettner, 2003; Vogt, 2003). The transduction pathway was identified as G-protein/IP3-based during the early 1990s (Boekhoff *et al*., 1990a, 1990b, 1993; Breer *et al*., 1990; Riesgo-Esgovar *et al*., 1995; Krieger and Breer, 2003). ORs were finally identified from the sequenced genome database of *Drosophila* (Clyne *et al*., 1999; Gao and Chess, 1999; Vosshall *et al*., 1999). Gustatory receptors were subsequently identified in a similar manner (Clyne *et al*., 2000; Dunipace *et al*., 2001; Scott *et al*., 2001). Now, having recently crossed the technological watershed of genome sequencing, we can expect to see this information expand rapidly across the Insecta.

3.15.3. Transduction Events

3.15.3.1. Receptors

3.15.3.1.1. Among noninsect species, odor molecules are detected by G-protein-coupled receptors The view that odor molecules are detected by membrane-bound receptor proteins was still being debated as recently as the early 1980s, and references to insect sensilla being light guides for infrared radiation being emitted from oscillating odor molecules still appear occasionally. But one really must credit Lancet for his seminal efforts in the early to mid-1980s, which firmly established the G-protein-coupled receptor (GPCR) model for odor detection. Working in vertebrates, Lancet and his group were the first to demonstrate odor-dependent increases in cAMP and the presence of G proteins in isolated olfactory neurons (Pace *et al*., 1985; Pace and Lancet, 1986). Work that followed established the existence of both cAMP and IP3 based G-protein transduction pathways in vertebrate olfaction (Jones and Reed, 1989; Dhallan *et al*., 1990; Bakalyar and Reed, 1991), setting the stage for the identification of 7-transmembrane domain GPCR odor receptors in the rat (Buck and Axel, 1991). The following decade saw the identification of odor receptors in vertebrates from fish, amphibians, birds, and mammals (Freitag *et al*., 1998; Mombaerts, 1999).

Vertebrate odor receptors comprise a large gene family, ranging from perhaps 100 members in fish to perhaps around 1300 in mammals (Zhang and Firestein, 2002; Young and Trask, 2002). These genes are quite conserved across the vertebrates; catfish receptors were initially identified using polymerase chain reaction (PCR) primers designed using rat OR sequences (Ngai *et al*., 1993), and a set of "universal" primers has been used to clone ORs from coelacanth to mammal (Freitag *et al*., 1998). Many details of this gene family, including its full size, are being revealed as full species genomes are made available. Interestingly, many OR genes have accumulated mutations rendering them nonfunctional pseudogenes, and the proportion of functional to nonfunctional genes varies considerably with the animal group and species (Frietag *et al*., 1998). For example, dolphins have no known functional OR genes (Frietag *et al*., 1998). Humans and mice have roughly similar number of OR genes, but in humans, nearly 70% are pseudogenes compared to perhaps 15% in mice (Young *et al*., 2002; Zhang and Firestein, 2002). The variation in functional members of this gene family can be considerable even among closely related species. Humans have as much as fourfold greater pseudogene content relative to other primates, a trend speculated to be related to differences in life history of the respective species (Rouquier *et al*., 2000; Gilad *et al*., 2003).

Vertebrate pheromone receptors are also GPCRs. The vertebrate vomeronasal organ (VNO), known in reptiles and mammals, is a distinct olfactory epithelium whose neuronal axons project to a distinct olfactory bulb (Halpern, 1987; Halpern *et al*., 1998; Tirindelli *et al*., 1998; Dulac, 2000; Takami, 2002). Three classes of unique GPCR genes have been identified as VNO receptors in mice: V1R, 80 genes; V2R, 50–100 genes; V3R, 100–120 genes (Dulac and Axel, 1995; Herrada and Dulac, 1997; Matsunami and Buck, 1997; Ryba and Tirindelli, 1997; Pantages and Dulac, 2000; Martini *et al*., 2001; Zufall *et al*., 2002). The V2R class of VNO receptors has also been identified in fish (Cao *et al*., 1998; Naito *et al*., 1998), and a V2R from goldfish

has been shown to interact with a variety of amino acids (Speca *et al.*, 1999). The V2R receptors, at least, are sufficiently conserved across the vertebrates to have permitted fish V2R genes to be identified using PCR primers based on mammalian V2R sequences (Cao *et al.*, 1998). An emerging view is that these VNO receptors may have originated as detectors of waterborne odor molecules, and have become increasingly specialized as pheromone receptors in higher vertebrates.

Chemoreceptor proteins of the nematode *Caenorhabditis elegans* are also GPCRs (Troemel *et al.*, 1995; Sengupta *et al.*, 1996; Wes and Bargmann, 2001). Analysis of the fully sequenced *C. elegans* genome indicates the presence of several families of functional GPCR chemoreceptors totaling nearly 800 genes (Robertson, 2000), which is remarkable considering that *C. elegans* has only 16 pairs of chemosensory neurons (Bargmann and Mori, 1997). Many nonfunctional *C. elegans* chemoreceptor genes are present in the genome; one gene family (*srh*) includes 214 functional genes and 90 pseudogenes (Robertson, 2000). One major difference between the chemoreceptor proteins of vertebrate and *C. elegans* is that vertebrate OR genes are more or less expressed one allele per neuron (Chess *et al.*, 1994) while *C. elegans* chemoreceptor genes may be expressed 40–50 per neuron (Robertson, 2000). Overall there seems to be remarkably little similarity between the chemoreceptor proteins of vertebrate and *C. elegans*, beyond the fact that they are GPCRs and they share sufficient structural features to suggest that both are 7-transmembrane domain proteins. Such extreme sequence divergence was discouraging to those hoping that common sequence domains between nematode and vertebrate OR genes would enable an expansion of these receptors to additional phyla, and suggests that rapid progress into other phyla may only be possible with the assistance of sequenced genomes.

3.15.3.1.2. Insect pheromones/odor molecules are detected by G-protein-coupled receptors The identification of GPCRs as odor receptors in vertebrates and nematodes (see Section 3.15.3.1.1), and the identification of a G-protein-coupled IP3 cascade in insect olfaction (see discussion below) set the stage for the identification of insect odor receptors in *Drosophila*. Efforts during the 1990s to identify ORs in a variety of insects using vertebrate or nematode OR sequences largely failed. One *Drosophila* gene that subsequently proved to be an OR was cloned by differential hybridization during the mid-1990s (DOR104/Or85e), but efforts to use this sequence to identify any additional genes were unsuccessful (Vosshall, 2003a). The problem was, and is, that it is difficult or impossible to recognize OR genes in an insect without the aid of the genome of that insect having been fully sequenced, obvious exceptions being close sibling species or recently duplicated gene pairs. *Drosophila* OR genes were identified from the partially sequenced genome, searching for any sequences that (1) were likely expressed, (2) encoded some degree of hydrophobicity, and (3) were otherwise unidentifiable. ORs emerged from the resulting pool, and were tentatively identified as such using histological methods (Clyne *et al.*, 1999; Gao and Chess, 1999; Vosshall *et al.*, 1999).

Analyses of the more or less fully sequenced genome of *Drosophila* have identified at least 61 candidate OR genes (*Dor*) (**Table 1**) (*Drosophila* Odorant Receptor Nomenclature Committee, 2000; Hill *et al.*, 2002; Vosshall, 2003a), and another 69 candidate GR genes (*Dgr*) a few of which are also likely involved in odor detection (Clyne *et al.*, 2000; Dunipace *et al.*, 2001; Scott *et al.*, 2001; Hill *et al.*, 2002); all appear to be GPCRs. The genome of *A. gambiae* contains at least 79 OR and 76 GR genes (Fox *et al.*, 2001, 2002; Hill *et al.*, 2002; Vosshall and Keller, 2003). Nine OR genes have been identified from a genome database of the moth *Heliothis virescens*, eight by comparison (BLAST) with the *Dor* sequences and one more from a low stringency cDNA library screen using the new *H. virescens* DNAs as probes; many more are presumably yet to be identified (Krieger *et al.*, 2002). Sequencing efforts are currently being applied to the genomes of several insects of diverse orders, both closely and distantly related to those above, which will greatly expand our knowledge of the insect OR gene family, as well as other olfactory gene families.

In adult *Drosophila*, olfactory neurons are restricted to the antennas (third segment) and maxillary palps. A total of about 1300 olfactory sensory neurons (OSNs) (1200 per antenna, 120 per palp) project axons to 43 glomeruli of the olfactory lobe (Venkatesh and Singh, 1984; Singh and Nayak, 1985; Stocker, 1994); all neurons expressing a given OR gene converge on one or in some cases a small subset of glomerulae (Gao *et al.*, 2000; Vosshall *et al.*, 2000; Bhalerao *et al.*, 2003). Overall there is little difference between male and female antennas/palps, though female antennas do have slightly more sensilla than males – 457 versus 419, primarily of the basiconic type (Shanbhag *et al.*, 1999). Of the 61 *Dor* genes, 39 are expressed in antennal neurons and nine are expressed in palp neurons (Clyne *et al.*, 1999; Gao and Chess, 1999; Vosshall *et al.*,

[a]*Drosophila* OR genes have been named after their map location. The *Drosophila* genome is artificially divided into 100 map regions: Chromosome 1 (C1), 1–20; C2, 21–60; C3, 61–99. Centromeres are located by map locations 40 and 80.
[b]OR genes residing near enough to define a gene cluster originating from probable ''recent'' gene duplications.
NA, not applicable.
Modified from Vosshall, L.B., **2003a**. Diversity and expression of odorant receptors in *Drosophila*. In: Blomquist, G.J., Vogt, R.G. (Eds.), Insect Pheromone Biochemistry and Molecular Biology. Academic Press, London, pp. 567–591.

1999, 2000); the remainder may be expressed at levels too low for the detection methods applied, or may express at specific developmental stages other than those examined, e.g., larval (Vosshall, 2003a), or may not be expressed at all. But clearly the majority of these OR genes are expressed and are apparently not pseudogenes. Each OSN is thought to express only one OR gene, though this is not fully confirmed; the one clear exception is *Dor83b* which actually appears to express in all olfactory neurons, coexpressing with other ORs (see below); on average, about 25 OSNs express any given OR gene (range 2–50 OSNs per OR gene) (Vosshall, 2003a). *Dor* genes encode proteins about 370–400 amino acids long; *Dor83b* is again an exception encoding a 486 amino acid protein. The presumptive 7-transmembrane domain of most Dor proteins contains a conserved motif Phe-Pro-X-Cys-Tyr-(X)20-Trp and the highest overall region of similarity among these proteins spans the 6- and 7-transmembrane domains (Vosshall, 2003a).

The insect OR genes are highly divergent. In general, the Dor proteins show about 17–26% sequence identity, with a few more similar (40–60%) presumably due to recent gene duplications (Vosshall, 2003a). A comparison of the *Anopheles* and *Drosophila* OR genes indicates that the majority of these dipteran genes segregate by species, the only clear ortholog being *Dor83b/AgamGPRor7* (Hill *et al.*, 2002). OR genes of the moth *H. virescens* are similarly divergent, sharing very low sequence identity with the Dor proteins and only 7–16% identity with each other (Krieger *et al.*, 2002). Analyses of all these proteins do suggest subgroupings based on sequence similarities (Hill *et al.*, 2002; Krieger *et al.*, 2002); whether these groupings reflect functional differences remains to be demonstrated.

The *Dor* genes are distributed throughout the *Drosophila* genome. Most reside in isolated locations, though about one-third of the *Dor* genes reside in clusters of two or three, presumably deriving from related gene duplications (Table 1). One extreme example of such a duplication is the OR*22a/22b* pair. These two genes are separated by

only about 650 bp, are 78% identical in their predicted amino acid sequences, and coexpress in the same OSNs (Dobritsa *et al.*, 2003).

The function of any of these genes as ORs is indirectly supported by their numbers, their divergent sequences, and their distributed expression among different OSNs (i.e., one OR per neuron). Dor43b has been immunologically localized to sensory dendrites (Elmore and Smith, 2001). Direct evidence that these genes encode ORs includes several electrophysiological studies. Ectopic expression of *Dor43a* in olfactory neurons using an OSN-specific driver gave increased responses in electroantennograms (EAGs) to several odor molecules including benzaldehyde, benzyl alcohol, cyclohexanol, and cyclohexanone (Störtkuhl and Kettler, 2001). Coexpression of Dor43a and a *Drosophila* G protein in frog oocytes made these oocytes sensitive to these same odor molecules (but not other odor molecules tested, and sham-injected oocytes were nonresponsive), and provided support that the ORs were indeed G protein coupled (Wetzel *et al.*, 2001).

Dor22a, Dor22b, and Dor47a have also recently been characterized (Dobritsa *et al.*, 2003). *Dor22a* and *Dor22b* are close gene neighbors (650 bp apart), share 78% amino acid sequence identity, and appear to coexpress in the same neuron in one class of basiconic sensilla (29 sensilla in female, 18 sensilla in male). Deletion/rescue electrophysiological studies suggest that Dor22a responds to ethyl butyrate, pentyl acetate, and ethyl acetate; however, no odor molecules (of 87 tested) were shown to stimulate Dor22b. This genetic system was shown to be useful for functionally characterizing other OR genes: expression of *Dor47a* using the *Dor22a* promoter and in a *Dor22a/Dor22b* null background demonstrated neuronal responsiveness to a set of odors novel to the *Dor22a*-expressing wild-type neuron. While these studies indicate that *Dor22a* and *Dor22b* coexpress, the only evidence presented that Dor22b might be functional is its identification in the sibling species *D. simulans*; observed conservation between the Dor22b orthologs in *D. melanogaster* and *D. simulans* was presumed possible only if selection was acting on the receptor genes, implying that the gene products are functionally active.

Dor83b is an OR gene that stands apart from the rest: it is expressed in all OSNs, it encodes a protein that is structurally distinct from other Dor proteins, and it is the only OR gene readily identified in diverse species: the fruit fly *D. melanogaster* (Dor83b: Vosshall *et al.*, 2000); the mosquito *A. gambiae* (AgamGPRor7: Hill *et al.*, 2002), the moth *H. virescens* (HR2: Krieger *et al.*, 2002), as well as the silk moths *Bombyx mori* and *A. polyphemus*, the honeybee *Apis mellifera,* the blowfly *Calliphor erythrocephala*, and the beetle *Tenebrio molitor* (Krieger *et al.*, 2003). These 83b/GPRor7/H2 proteins are 64–88% identical, differing from one another in a phylogenetically consistent manner (Krieger *et al.*, 2003). As this gene expresses in all OSNs, always coexpressing with one of the other OR genes, it is presumably not functioning as the other OR proteins do in interacting with an odor ligand. Several functions for this gene have been speculated including that (1) it forms a heterodimer with the ligand-sensitive OR, (2) that it activates a second messenger pathway in a ligand independent manner, (3) that it helps in the trafficking of OR proteins to the correct site in the dendritic membranes (discussed by Krieger *et al.*, 2003; Vosshall and Keller, 2003; Vosshall, 2003a). None of these functions has been verified as of early 2000s.

Insect OR genes partially define the phenotypes of OSNs, but they apparently do not contribute to the determination of these phenotypes. **Figure 1** summarizes general features of the brain neurocircuitry of the insect olfactory pathway and includes references to many elegant studies. Each glomerulus of the olfactory lobe receives axons belonging to OSNs of a single phenotype; all OSNs converging on an individual glomerulus are thought to express the same OR gene (Gao *et al.*, 2000; Vosshall *et al.*, 2000; Bhalerao *et al.*, 2003). The positions of these glomerulae are more or less constant from animal to animal, and in some cases the preservation of these positions may have a functional significance in coding (Hansson *et al.*, 1992, 2003; Carlsson and Hansson, 2003a, 2003b). Furthermore, a recent study has shown that the projection neurons emanating from these glomerulae terminate their axons in the lateral protocerebrum in a spatially restricted manner that to some degree maintains the spatial organization of the olfactory lobe (Wong *et al.*, 2002). In vertebrates, OR genes have been shown to influence the projection of OSNs to specific glomerulae; neurons missexpressing the appropriate OR gene miss or fail altogether to target a specific glomerulus (Mombaerts *et al.*, 1996; Wang *et al.*, 1998; reviews: Korsching, 2002; Vosshall, 2003a, 2003b). The *Drosophila* ORs, however, apparently do not have this capability. OSNs expressing Dor22a/Dor22b target an identifiable glomerulus; these OSNs still target this glomerulus in a Dor22a/Dor22b deletion mutant whether or not an alternative OR gene is expressed in these neurons (Dobritsa *et al.*, 2003). In insects, correct targeting of OSNs appears to function independent of the OR genes.

3.15.3.1.3. Gustatory neurons detect chemostimulants using G-protein-coupled receptors Perhaps 69 GPCRs have been identified as candidate gustatory receptors in the *Drosophila* genome (Clyne *et al.*, 2000; Dunipace *et al.*, 2001; Scott *et al.*, 2001; Hill *et al.*, 2002); 76 were identified in the *A. gambiae* genome (Hill *et al.*, 2002). The expression of a subset of the *Drosophila* GRs has been characterized; these are associated with a variety of tissues including the ventral pits, gut, mouth, dorsal, and terminal organs of larvae and labellum, cibarial organs, labral organ, legs, and wings of adults (Dunipace *et al.*, 2001; Scott *et al.*, 2001). One, *Gr21D1*, expresses in antennas, associating with a neuron that projects to a specific glomerulus in the olfactory lobe (Scott *et al.*, 2001) However, all others examined which express in head tissues associate with neurons that project to the subesophageal ganglion (SEG) (Stocker, 1994). Like the antennal lobe, the SEG is organized into a discrete number of glomerulae, i.e., seven (Shanbhag and Singh, 1992). However, unlike the antennal system, GR expressing neurons arborize into multiple SEG glomerulae (Singh and Nayak, 1985; Singh, 1997; Dunipace *et al.*, 2001; Scott *et al.*, 2001). Only one GR gene has been functionally characterized; *Gr5a* encodes a trehalose receptor (Dahanukar *et al.*, 2001; Ueno *et al.*, 2001). Interestingly, in both studies *Gr5a* was chosen for study because it is tightly linked to another gene, *tre* (Ishimoto *et al.*, 2000), which had previously been implicated as a trehalose receptor but has no sequence similarity to the putative *Drosophila* GR genes. *Gr5a* expresses in labellar sensilla. The GRs of *Drosophila* are highly divergent, ranging from 15% to 25% in sequence identity. Considering such divergence and the number of genes, these animals presumably “taste” a broad range of molecules that might further be quite different between larvae and adults. Insect taste is undoubtedly much more complex than may be implied by the understatement that taste discriminates the modalities of sweet, sour, salty, and bitter (Singh, 1997). As GRs are identified from a broad range of insects, they might be expected also to be highly divergent, driven so by the chemistry of host plants utilized by various insect groups. Whether any of these GRs are involved in pheromone detection remains to be determined.

3.15.3.2. Second Messenger Pathways

3.15.3.2.1. Pheromone/odor transduction is mediated by a G protein-based IP3 pathway The identification of GPCR odor receptors in both vertebrates and invertebrates was preceded by the identification of odor activated G protein/second messenger cascades. Two G-protein-coupled transduction pathways have been identified in olfactory systems of vertebrates and arthropods: (1) G protein dependent activation of phospholipase C (PLC) with the subsequent production of IP3; or (2) G protein dependent activation of adenylate cyclase with the subsequent production of cAMP (Krieger and Breer, 2003). Both pathways exist in vertebrates, and in lobsters both pathways are thought to coexist in the same olfactory chemosensory neurons (Fadool and Ache, 1992; Michel and Ache, 1992; Boekhoff *et al.*, 1994; Hatt and Ache, 1994). In insects, only the G-protein-coupled IP3 pathway illustrated in **Figure 2c** has been demonstrated for both pheromones and nonpheromonal odor molecules.

When pheromone or other odor molecules were applied to homogenates of cockroach or moth antennas, a rapid rise in IP3 was observed (Boekhoff *et al.*, 1990a, 1990b, 1993; Breer *et al.*, 1990). This rise in IP3 was assumed to be mediated by a receptor activated G protein. The Gα subunits Go and Gq have been identified in or cloned from antennas of cockroach, fly, and moth (Breer *et al.*, 1988; Boekhoff *et al.*, 1990b; Raming *et al.*, 1990; Talluri *et al.*, 1995), and Gq-like proteins have been immunohistologically visualized in the dendritic membranes of pheromone sensory neurons in the silk moths *B. mori* and *A. pernyi* (Laue *et al.*, 1997). To affect changes in IP3 levels, a receptor activated Gα subunit would activate the membrane-bound enzyme PLC, which in turn would cleave the membrane lipid phosphotidyl inositol 4,5-biphosphate (PIP2) to membrane-bound diacylglycerol (DAG) and cytosol soluble IP3 (see **Figure 2c**). A PLC *Drosophila* mutant, *norpA*, has been shown to be severely impaired in odor detection (Riesgo-Escovar *et al.*, 1995). PLC has also been immunologically identified by Western blot in homogenates of olfactory dendrites of the moth *A. polyphemus* (Maida *et al.*, 2000). The classic action of IP3 is to interact with Ca^{2+} channels, also referred to as IP3 receptors; such receptor/channels have been immunohistologically visualized in the dendritic membranes of pheromone sensory neurons of *B. mori* and *A. pernyi* (Laue and Steinbrecht, 1997). In olfactory neurons of the locust *Locusta migratoria*, extracellular application of odors or intracellular application of IP3 generated an increase in the inward membrane conductance of cations, including Ca^{2+} (Wegener *et al.*, 1997). In cultured adult olfactory neurons of the moth *M. sexta*, an IP3-dependent inward Ca^{2+} current was observed to precede general inward cation currents (Stengl, 1994). Thus, by 1999, all the components depicted in the **Figure 2c** scheme have been

identified, with the exception of the odor receptors themselves.

A limited number of studies have investigated the role of cAMP in insect olfactory transduction, but no increases in cAMP have been observed on stimulation with pheromone or other odor molecules in insects (Ziegelberger *et al.*, 1990; Boekhoff *et al.*, 1993). Curiously, cyclic nucleotide gated ion channels have been identified in insect antennas, and in fact is localized to olfactory receptor neurons (Baumann *et al.*, 1994; Krieger *et al.*, 1997). This may imply that a cAMP pathway does exist for certain odorants; cAMP olfactory pathways are known in lobsters (Michel and Ache, 1992; Hatt and Ache, 1994) and vertebrates (e.g., Jones and Reed, 1989; Bakalyar and Reed, 1990; Boekhoff and Breer, 1992; Rossler *et al.*, 2000b). Alternatively, these cyclic nucleotide gated channels may function in other roles, perhaps as part of neuromodulatory pathways in the neuronal cell bodies, or in the maintenance of background neural activity and sensitivity (Krieger *et al.*, 1997). The role of cGMP in pheromone transduction has also been demonstrated, but it appears to have a modulatory role in adaptation or desensitization rather than participating in primary transduction (see Section 3.15.3.2.2) (Ziegelberger *et al.*, 1990; Redkozubov, 2000; Stengl *et al.*, 2001; Dolzer *et al.*, 2003). As of now, there is little evidence that cyclic nucleotides act in a primary capacity in the transduction of pheromone or other odor signals in insects.

3.15.3.2.2. Pheromone/odor transduction is modulated by G-protein based second messenger processes Second messenger processes have dynamic properties due to the number of divergent pathways they can initiate; few of these potential pathways have been investigated. These might be forward pathways, where signal molecules such as IP3 might interact with secondary targets, perhaps altering the future response characteristics of the neuron, or they might be backward pathways, downregulating the activity of processes just initiated (e.g., the receptor mediated G protein-coupled pathway). The physiological dynamics of pheromone adaptation has recently been investigated in the moth *B. mori* with respect to stimulus concentration and duration (Dolzer *et al.*, 2003). Yet, few modulatory processes have been examined thoroughly in insect olfaction. Two loose ends depicted in **Figure 2c** are the βγ subunits of the G-protein (Gβγ) complex and DAG. "Gβγ is now known to directly regulate as many different protein targets as the Gα subunit" (Clapham and Neer, 1997). In vertebrates, Gβγ has been shown to activate G-protein-coupled inwardly rectifying K^+ channels (GIRKs) (Salvador *et al.*, 2003). Gβγ has been shown to activate regulators of G-protein signaling (RGS) proteins which in turn activate GAP protein (GTPase activating protein) which regulates the GTPase activity in the Gα subunit (turning off Gα activity) (Witherow and Slepak, 2003). Gβγ has been shown to regulate G-protein-coupled receptor kinases (GRKs) which phosphorylate and downregulate GPCRs (Inglese *et al.*, 1992; Pitcher *et al.*, 1998; Eichmann *et al.*, 2003). Gβγ has been shown to regulate the activities of certain PLC enzymes and the subsequent production of IP3 (Akgoz *et al.*, 2002). In vertebrate chemoreception, Gβγ has been shown to regulate PLC activity in mammalian vomeronasal neurons (Runnenburger *et al.*, 2002) and in bitter taste neurons (Rossler *et al.*, 2000a). Active Gβγ signaling in insect olfaction has yet to be reported.

Arrestins are proteins that bind to the phosphorylated state of a GPCR, and can mediate the uncoupling of GPCRs from G proteins (desensitization) (Inglese *et al.*, 1993; Pippig *et al.*, 1993; Freedman and Lefkowitz, 1996) as well as the internalization of GPCRs (with presumed subsequent dephosphorylation in microsomes with subsequent recycling of the receptor, i.e., resensitization) (Ferguson *et al.*, 1996). In an IP3 mediated pathway, GPCR phosphorylation may be mediated by GIRKs, which may be mediated by Gβγ (see above). Arrestins have been identified in insect antennas and shown to be critical in the olfactory transduction process in *Drosophila* and *A. gambiae* (Merrill *et al.*, 2002). In this study, an arrestin was cloned from *A. gambiae*, and was shown to express in both olfactory and visual sensory neurons. Of three *Drosophila* arrestins, *DmArr1* and *DmArr2* were shown to express in both visual and olfactory tissue while *DmKrz* was nonvisual but also expressed in olfactory tissue. A double mutant ($arr1^2; arr2^3$) showed reduced EAG response to butanol and ethyl acetate, suggesting that arrestins play a key role in olfactory transduction in these animals (Merrill *et al.*, 2002).

DAG is another product of the IP3 pathway that has potential targets. DAG is classically considered as a regulator of protein kinase C (PKC), but may also interact with membrane lipases to induce the release of polyunsaturated fatty acids (e.g., arachidonic acid) which may activate certain ion channels/membrane conductances. These ion channels may also be sensitive to levels of PIP2, regulated by PLC (Hardie, 2003; Krieger and Breer, 2003; Nilius *et al.*, 2003). Recently, a membrane permeable analog of

DAG, 1,2-dioctanol-*sn*-glycerol (DOG), was shown to elicit action potentials in pheromone sensitive neurons of the moth *B. mori* (Pophof, 2002; Pophof and van der Goes van Naters, 2002), suggesting an active role for DAG in insect olfactory transduction.

Prolonged but only moderately elevated cGMP levels in response to applied sex pheromone have been measured in the antennas of the moths *A. polyphemus* and *B. mori* (Ziegelberger *et al.*, 1990). Application of dibutyryl cGMP inhibited the response of *B. mori* pheromone sensitive neurons to pheromone (Redkozubov, 2000). These findings suggest a role for cGMP in modulating the response to sex pheromone. Pheromone-dependent elevation of cGMP levels was observed immunologically to occur in only a very small subpopulation of known pheromone sensitive sensilla (about 1% of sensilla trichoidea) of male antennas of the moth *M. sexta* (Stengl *et al.*, 2001). In these same studies, the location of NO-sensitive soluble guanylate cyclase was determined to be entirely restricted to a population of sensilla chaetica but absent from sensilla trichoidea. Thus, while there appears to be a role for cGMP in pheromone transduction, the mechanism underlying that role or its value to pheromone perception remains unresolved. However, cGMP appears to regulate olfactory transduction in a subpopulation of rat olfactory neurons that have behavioral significance (review: Zufall and Munger, 2001), suggesting that perhaps the subpopulation of neurons in *M. sexta* which shows a pheromone-dependent rise in cGMP may similarly serve a specialized behavioral function (Stengl *et al.*, 2001).

3.15.4. Perireception Events

Figure 2b summarizes a number of biochemical reactions that interact directly with pheromone and odor molecules in the extracellular space of the sensillum interior. Each sensillum contains at least three classes of protein with evolutionarily designed binding sites for these ligands: OBPs, ORs, and ODEs. Individual sensilla contain multiple members of each class, and the phenotypes of functionally distinct sensilla can be defined by the unique combinations of these gene products. These proteins comprise a biochemical network designed to process environmental signals. This network serves as a genetic interface between the animal and its environment, its components designed and organized by evolutionary selection; the single purpose of these gene products has allowed selection to proceed unconstrained from the need to balance requirements of other competing functions.

3.15.4.1. Odor Transport by Odorant Binding Proteins

Insect OBPs comprise a multigene family that includes a group of small hydrophilic proteins which bind and transport small hydrophobic ligands. Vertebrates also possess proteins that function as OBPs; however, vertebrate and insect OBPs are evolutionarily unrelated (Tegoni *et al.*, 2000; Ramoni *et al.*, 2001). The first insect OBP identified was the PBP of the silk moth *A. polyphemus* (Vogt and Riddiford, 1981). This 14 kDa protein appeared to be specific to the male antenna, was perhaps the most abundant soluble protein in the antenna, was located in the aqueous extracellular fluid that bathed the pheromone-sensitive neurons, and could bind sex pheromone. The concentration of *Apol*PBP within the sensillum fluid was estimated to be about 10 mM (Klein, 1987). Additional PBPs were subsequently identified by tissue specificity and N-terminal sequence from the moths *Hyalophora cecropia*, *B. mori*, *Lymantria dispar*, *M. sexta*, and *Orgyia pseudosugata* (Vogt, 1987; Vogt *et al.*, 1989, 1991a); the first full length OBP sequences were obtained for *M. sexta* PBP1 (Györgyi *et al.*, 1988) and *A. polyphemus* PBP1 (Raming *et al.*, 1989). The identification of two PBPs in *L. dispar* was the first indication of multiple PBP genes within a single species (Vogt *et al.*, 1989). The identification and cloning of the general odorant binding proteins GOBP1 and GOBP2 (Vogt and Lerner, 1989; Breer *et al.*, 1990; Vogt *et al.*, 1991a, 1991b) were the first indication that OBPs were members of a multigene family. These data on lepidopteran OBPs provided a basis for identifying the first OBPs in *Drosophila* (OS-E and OS-F: McKenna *et al.*, 1994; PBPRP1-5: Pikielny *et al.*, 1994; LUSH: Kim *et al.*, 1998). Collectively, the OBPs described above might be viewed as the "gold standard" OBPs against which all others are compared.

One hallmark feature of these proteins that is almost universally cited when presenting new OBP sequences is the positionally conserved presence of six cysteines (first noted by Breer *et al.*, 1990). In more recent genomic analyses, the presence of these six cysteines plus a similar size and an acceptable result from BLAST analysis has been viewed as sufficient to consider these genes members of an OBP gene family (Galindo and Smith, 2001; Graham and Davies, 2002; Hekmat-Scafe *et al.*, 2002).

OBPs have now been identified in at least 41 species from orders throughout the Neopterous insects (**Table 2**; **Figures 3** and **4**), suggesting that they are common elements in olfactory sensilla of

at least 98% of all insect species (Vogt *et al.*, 1999). OBPs have yet to be identified in preneopterous lineages (e.g., Odonata – dragonflies, Ephemeroptera – mayflies, Thysanura – silverfish, Archaeognatha – bristletails). Direct cloning and genome analyses have identified more than 50 OBP-related genes in *Drosophila* (McKenna *et al.*, 1994; Pikielny *et al.*, 1994; Kim *et al.*, 1998; Galindo and Smith, 2001; Graham and Davies, 2002; Hekmat-Scafe *et al.*, 2002; Vogt *et al.*, 2002). A similar number have been identified in *A. gambiae* based on genome analyses (Robertson *et al.*, 2001; Biessmann *et al.*, 2002; Vogt, 2002; Xu *et al.*, 2003). Most of these sequences are highly divergent, though some sequences are clearly the products of recent gene duplications based on sequence similarity, conserved exon structure, and clustered chromosomal location (e.g., *Drosophila* OS-E/OS-F: Hekmat-Scafe *et al.*, 2000, 2002; Vogt, 2002; Vogt *et al.*, 2002). Like the *Dors*, the *Drosophila* OBPs are distributed throughout the genome (see Table 2, where *DrosOBP* genes are named for their map location) (Vogt, 2003). The majority of OBPs that have been sequenced in the Lepidoptera are PBPs and GOBPs which are distinct but share common sequence motifs; however, sequencing efforts have identified 13 OBP genes in *M. sexta*, including three PBPs, GOBP1, GOBP2, and another eight that are as highly divergent as the dipteran OBPs (Györgyi

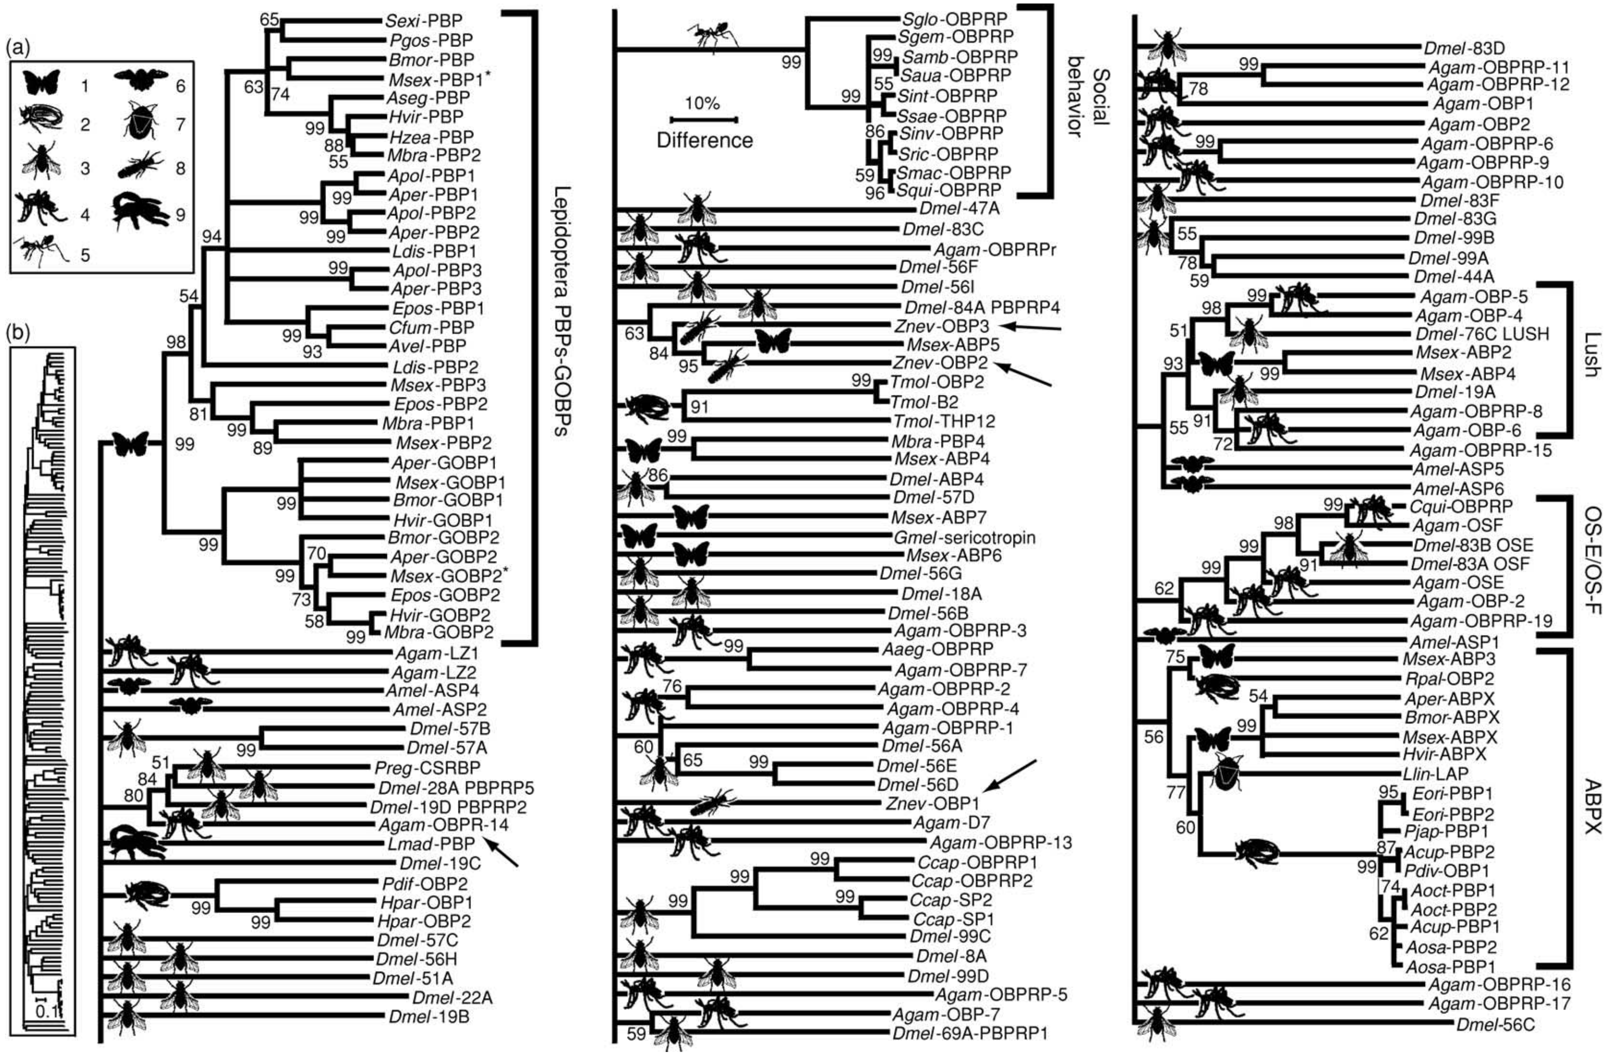

Figure 3 A neighbor-joining tree of most OBPs listed in Table 2; bootstrap support is based on 1000 replicates and only branches with >50% support are shown. A single tree is shown, broken into thirds to fit the page. Insert (a) is a key to the taxa. Insert (b) is the uncollapsed tree (taxa not indicated) to illustrate full branch lengths (percent sequence differences). A size bar indicating 10% sequence difference is shown. Named branch clusters (e.g., ABPX) are referred to in the text.

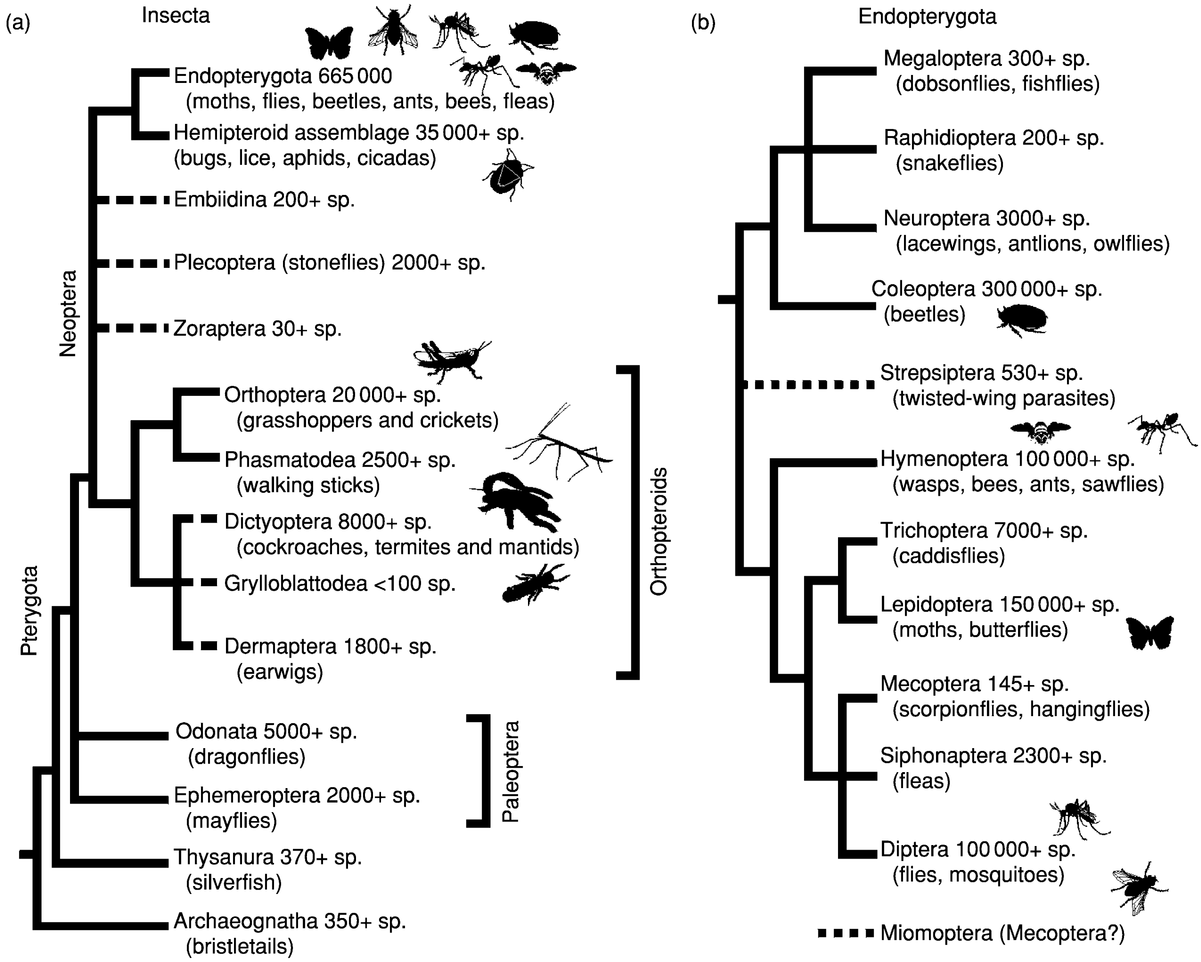

Figure 4 Overview of insect phylogeny (after Boudreaux, 1979; Hennig, 1981; Kristensen, 1991). In (a), the representation of a monophyletic orthopteroid group is considered debatable (Maddison and Maddison, 1998); this group was suggested by Boudreaux (1979) and Hennig (1981), but was not included by Kristensen (1991) due in part to uncertainties regarding the relationships of the Plecoptera. The monophyletic division of Endopterygota (holometabolous insects) (Kristensen, 1991; Whiting *et al.*, 1997) is supported by most authors in part because of the unique development in this group; all members undergo a complete metamorphosis from the nonreproductive larval stage to the reproductive adult stage. A shared common ancestor for the Endopterygota and the hemipteroid lineages is suggested by morphological (Hennig, 1981; Kristensen, 1991; Whiting *et al.*, 1997) and molecular data (Whiting *et al.*, 1997). In (b), two supported endopterygote lineages are shown, one including the Coleoptera and a second including Hymenoptera, Diptera, and Lepidoptera. The fossil record suggests that the orthopteroids are more ancient than most endopterygote orders (late Carboniferous vs. early Permian); among the Endopterygota, the Coleoptera (Permian) are more ancient than the Diptera/Lepidoptera lineage, and the Diptera (Triassic) are more ancient than the Lepidoptera (Jurassic) (Kukalová-Peck, 1991; Labandeira and Sepkoski, 1993). The greater part of molecular or biochemical based olfactory research has been done on a subset of these orders (noted by the insect symbols). Numbers of named species in each lineage are shown, taken from various entries in *The Insects of Australia* (Achterberg and CSIRO staff, 1991); these numbers are generally viewed as gross underestimates, but accurately reflect the relative success of the respective lineages.

et al., 1988; Vogt *et al.*, 1991b, 2002; Robertson *et al.*, 1999). Undoubtedly, full genome analysis of a lepidopteran species will identify many more.

Not all OBPs are involved in odor detection. The genes listed in Table 2 include serum proteins from the medfly *Ceratitis capitata* (Y08954 and Y19146: Thymianou *et al.*, 1998) and the beetle *T. molitor* (THP12: Rothemund *et al.*, 1999; Graham *et al.*, 2001); accessory gland proteins from *T. molitor* (B1 and B2: Paesen and Happ, 1995), and the *Drosophila* protein PBPRP2 which is localized in nonchemosensory tissues or spaces (Park *et al.*, 2000). Galindo and Smith (2001) examined the expression of 34 candidate *Drosophila* OBPs using a GAL4/UAS system, driving reporter gene expression using presumptive OBP promoters. Nine of these OBP-regulatory constructs expressed only in “chemosensory tissue” (sensilla of antennas and palps), four expressed only in “gustatory tissue” (sensilla of legs and wings), nine expressed in both tissues, five expressed

in nonsensillar tissue, and seven did not express at all, perhaps due to inappropriate choice of regulatory region or the genes in question being pseudogenes (Galindo and Smith, 2001). Another recent study identified seven OBP-related genes that express in gustatory sensilla of the fleshfly *Boettcherisca peregrina* (Koganezawa and Shimada, 2002 (not included in **Table 2**). Clearly, though many OBP genes are assumed to express proteins which have an important role in odor detection, assigned membership in this gene family does not necessarily imply an olfactory or even chemosensory function; although, at the very least such membership should imply common ancestry (i.e., the genes all derived by gene duplications originating from one common ancestral gene).

3.15.4.1.1. General properties of odorant binding proteins In general, OBPs are small, water-soluble, extracellular proteins around 14 kDa, and ranging between 120 and 150 amino acids long. OBPs presumably bind small ligands, and if involved in odor detection, those ligands are presumably odor molecules. OBPs are expressed with leader sequences which are removed during secretion. Most OBPs contain six cysteines in a certain asymmetric pattern, which has become a diagnostic feature of OBPs; these cysteines form disulfide bonds which stabilize the functionally relevant three-dimensional structure of the protein (Leal *et al*., 1999; Briand *et al*., 2001a, 2001b). OBPs involved in odor detection are expressed in sensilla support cells and secreted by these cells into the aqueous sensilla lumen (Vogt *et al*., 2002).

The structure of OBPs has been characterized by X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy. X-ray analysis of the moth *B. mori* PBP1 (*Bmor*PBP1) revealed six α-helix units stabilized by three disulfide bonds; a flask-shaped pheromone binding pocket is formed by four α-helices, and in an early study, another α-helical unit appeared to cover the narrow pocket opening (Sandler *et al*., 2000). Also, *Bmor*PBP1 formed a dimeric structure in the crystal (also suggested by Leal, 2000). Similar structures have been determined for antennal OBPs from the honeybee and cockroach (Lartigue *et al*., 2003a, 2003b), as well as a hemolymph OBP homolog (THP12) of unknown function from the beetle *T. molitor* (Rothemund *et al*., 1999; Graham *et al*., 2001). Disulfide bridges join cysteines 1–3, 2–5, 4–6 in *Bmor*PBP1 (Leal *et al*., 1999); the same disulfide bridge pattern has also been observed in the honeybee OBP ASP2 (Briand *et al*., 2001a, 2001b). Thus, even for OBP relatives with highly divergent sequences, the overall structural features appear remarkably conserved. Additional structural information is presented below (see Section 3.15.4.1.3).

3.15.4.1.2. Differential expression of odorant binding proteins The unique expression of PBPs in antennas, their localization within olfactory sensilla, and their ability to bind sex pheromones was strong evidence of their role in pheromone detection (e.g., Vogt and Riddiford, 1981; Vogt *et al*., 1989). The identification of PBPs and GOBPs with their sexual dimorphic expression patterns suggested that different OBPs may associate with sensilla of distinct odor phenotypes (Vogt *et al*., 1991a). For example, in the moth *M. sexta*, PBP1 and GOBP2 express in different functional classes of olfactory sensilla (Vogt *et al*., 2002) (**Figure 5**). Initially, PBPs were thought to be male specific, but it is now clear that while PBPs associate with pheromone sensitive sensilla in males, PBPs also express in female antennas where their role is unknown. It is possible that PBPs expressing in females may function in the monitoring of pheromone release (Callahan *et al*., 2000; Vogt *et al*., 2002). Certain families of Lepidoptera, especially the noctuids, display an almost total sex indifference in antennal levels of PBP expression.

The distribution of PBPs, GOBP1, GOBP2, and ABPX proteins have been characterized in several moth species using immunohistochemistry and electron microscopy; PBP proteins are present in the lumen of long trichoid sensilla, GOBP2 and ABPX proteins are present in the lumen of subsets of basiconic sensilla, and GOBP1 can be present in both trichoid and basiconic sensilla (Steinbrecht *et al*., 1995; Steinbrecht, 1996; Laue and Steinbrecht, 1997; Maida *et al*., 1999; Zhang *et al*., 2001). This broad expression of GOBP1 in both basiconic and trichoid sensilla was also observed by *in situ* hybridization in *M. sexta* (Vogt *et al*., 2002). Similar patterns have been described in Diptera. In *Drosophila*, OS-E, OS-F, and LUSH coexpress in trichoid sensilla, OS-E and OS-F but not LUSH coexpress in intermediate sensilla, and PBPRP5 expresses in a subset of basiconic sensilla (Hekmat-Scafe *et al*., 1997; Park *et al*., 2000; Shanbhag *et al*., 2001a). Galindo and Smith (2001) tested the expression patterns of 34 presumptive OBP promoters in *Drosophila*; nine drove expression in olfactory tissue alone (antenna and palps) while another nine drove expression in both olfactory and gustatory (wings and legs) tissues. These studies show that OBPs differentially express in sensilla that have diverse odor specificities, and therefore the OBPs contribute to the overall odor-specific phenotypes of the sensilla.

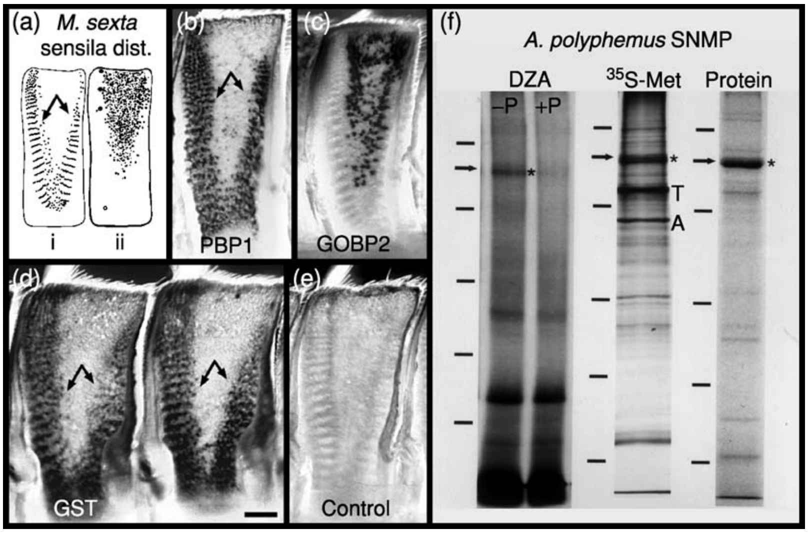

Figure 5 *In situ* hybridizations (wholemount) of *Msex*PBP1, *Msex*GOBP2, and *Msex*GSTolf in adult male *M. sexta* antenna (a–e) and visualizations of sensory membrane proteins of *Antheraea polyphemus*, including *Apol*SNMP1 (f). Expression of *M. sexta* PBP1, GOBP2, and GST. (a) Shows the nonoverlapping distribution of pheromone sensitive long trichoid sensilla (i) vs. other olfactory sensilla (after Lee and Strausfeld, 1990). (b) and (c) show the nonoverlapping expression of *Msex*PBP1 and *Msex*GOBP2 (Vogt *et al.*, 2002), and (d) shows the PBP-like expression of *Msex*GSTolf (Rogers *et al.*, 1999). Arrows point to pheromone-sensitive sensilla. (e) shows a control *in situ* using an noninsect probe. Scale bar = 100 μm. (Modified from Rogers, M.E., Jani, M.K., Vogt, R.G., **1999**. An olfactory specific glutathione *S*-transferase in the sphinx moth *Manduca sexta*. *J. Exp. Biol. 202*, 1625–1637.) (f) Visualizations of *A. polyphemus* SNMP1. Three experiments characterizing proteins of the receptor membranes of olfactory neurons of male *A. polyphemus*. DZA: dendrite membranes were photolabeled with [^{3}H]-DZA in the absence (−P) and presence (+P) of excess nonradioactive pheromone; asterisk marks SHMP69 thought to be a candidate pheromone receptor (fluorogram, from Vogt *et al.*, 1988). ^{35}S-Met: dendrite membrane proteins metabolically labeled with injected ^{35}S-Met, revealing a prominent band near 69 kDa (asterisk) as well as tubulin (T) and actin (a) (Vogt, unpublished fluorogram; for details of method see Vogt *et al.*, 1989). Protein: membranes were isolated from olfactory sensilla isolated from 800 male antennas of animals attracted to female moths releasing sex pheromone. One-tenth of this preparation was analyzed revealing an abundant protein near 69 kDa (asterisk) visualized by Coomassie Blue staining; this band (*Apol*SNMP1) was electroblotted and sequenced (Rogers *et al.*, 1997). Arrows identify the position of a 69 kDa marker in each gel.

3.15.4.1.3. Functional studies of odorant binding proteins The suggestion that OBPs function as odor transporters was first proposed (Vogt *et al.*, 1985) as an alternative to a model that was prevalent at the time in which pore tubules served as the pheromone conduit from sensillum surface to OSN membrane (Ernst, 1969; Steinbrecht and Müller, 1971; Kaissling, 1974, 1986; Kaissling and Thorson, 1980; Keil, 1982; Steinbrecht, 1997). Studies suggested that pore tubule to neuron contacts were quite rare (Keil, 1982), and their visualization highly dependent on tissue fixation in histological preparations (Steinbrecht and Müller, 1971; Steinbrecht, 1980; Keil, 1982). In the likely absence of such a pore tubule delivery system, the presence of a soluble binding protein and a potent pheromone degrading enzyme suggested the model presented in Figure 2.

In this new model, based on studies using the moth *A. polyphemus*, the hydrophobic pheromone molecules were solublized into the aqueous sensillum lumen by PBPs, transported by the PBPs to ORs in the OSN membranes, and subsequently degraded by ODEs (Vogt *et al.*, 1985). ODE kinetic properties were characterized, and the pheromone half-life within the sensillum was estimated at below 15 ms (Vogt *et al.*, 1985). An even shorter half-life was later estimated for pheromone within sensilla of the moth *M. sexta* (Rybczynski *et al.*, 1989). The ability of the *A. polyphemus* ODE to degrade pheromone was characterized at various pheromone concentrations and in the presence of various PBP concentrations (Vogt and Riddiford, 1986a). Results suggested that PBP did not protect pheromone from ODE through irreversible binding, but rather by mass action (i.e., PBP getting in the way of SE based on an estimated 1000-fold difference in concentrations for the two proteins). Results also suggested a pheromone-PBP K_D in the 1–10 μM range (Vogt and Riddiford, 1986a).

This function of PBPs as pheromone transporters in pheromone detection became generalized with the identification of PBPs from diverse species, and was extended to the detection of plant volatiles with the multispecies identification of GOBP1 and GOBP2 protein families (Vogt *et al.*, 1991a). The

identification of OBPs in *Drosophila* (McKenna *et al.*, 1994; Pikielny *et al.*, 1994) expanded these roles beyond the Lepidoptera; the identification of an OBP in the hemipteran *Lygus lineolaris* suggested that OBPs were present throughout the holometabolous and hemipteran lineages (Vogt *et al.*, 1999), and the recent identification of OBPs in orthopteroid insects (Ishida *et al.*, 2002a; Ban *et al.*, 2003b; Rivière *et al.*, 2003) argues that OBPs function throughout the neopteran lineages, and thus presumably the vast majority of eukaryotic organisms (Erwin, 1982; Novotny *et al.*, 2002) (**Figure 4**). Finally, significant number of OBPs with divergent sequences have been identified in *M. sexta, D. melanogaster*, and *A. gambiae* (**Table 2**); such numbers are consistent with expectations for odor receptors, i.e., that there should be many odor receptors to deal with the number of odorous ligands an animal detects (Buck and Axel, 1991; Vosshall *et al.*, 1999). The number and diversity of OBP genes (**Table 2**, **Figure 3**) coupled with their differential expression in olfactory sensilla during a time when odors are being detected (**Figure 5**) argues that they play a central role in odor processing. But what is that role?

Pheromone binding has been demonstrated for PBPs from diverse species, including moths (Vogt and Riddiford, 1981; Vogt *et al.*, 1989; Maïbèche-Coisné *et al.*, 1997, 1998; Jacquin-Joly *et al.*, 2000, 2001), honeybee (Danty *et al.*, 1999), and beetle (Nikonov *et al.*, 2002). Binding constants between pheromone and PBP have been estimated as low as 60 nM (Kaissling, 1986) but more typically in the range of 0.5–10 μM (Vogt and Riddiford, 1986a; Du and Prestwich 1995; Plettner *et al.*, 2000; Kowcun *et al.*, 2001; Campanacci *et al.*, 2001a; Bette *et al.*, 2002). Values of K_D of 20–30 μM have also been determined for certain compounds and conditions (Kowcun *et al.*, 2001; Bette *et al.*, 2002); the K_D for a PBP of *Mamestra brassicae* was estimated at 0.2 μM (Campanacci *et al.*, 2001a). Two PBPs of the gypsy moth *L. dispar* were shown to differentially bind the two optical enantiomers of disparlure, the gypsy moth sex pheromone (Vogt *et al.*, 1989; Plettner *et al.*, 2000). Two PBPs of the silk moth *A. pernyi* were shown to differentially bind components of the sex pheromone of that species (Du *et al.*, 1994; Du and Prestwich, 1995). Specific ligand binding has also been demonstrated for the GOBP2 protein of *M. sexta* (Feng and Prestwich, 1997) and a GOBP of the moth *M. brassicae* (Bohbot *et al.*, 1998). *A. polyphemus* PBP1 (*Apol*PBP1) displayed different endogenous tryptophan based fluorescence in binding studies with three different pheromone components (Bette *et al.*, 2002). Differential specificities of the binding sites of PBPs of the moths *M. brassicae* and *A. polyphemus* have been demonstrated in competition studies examining the displacement of a fluorescent probe, 1-aminoanthracene (AMA) by pheromone components and nonpheromonal fatty acids (Campanacci *et al.*, 2001a). One OBP from *Drosophila*, Lush, has been shown to be necessary for the appropriate behavioral response to alcohol; *lush* mutants do not display the normal wild-type avoidance of alcohol (Kim *et al.*, 1998; Kim and Smith, 2001). *Lush* has also been shown to express in trichoid sensilla of the adult antenna, coexpressing with OS-E and OS-F (Shanbhag *et al.*, 2001a). Nevertheless, for all these studies, the vast majority of OBPs remain uncharacterized, either biochemically or genetically.

Pheromone binding may be regulated by pH dependent conformational changes in PBP. In *Bmor*PBP1 the pheromone binding pocket is formed by four α-helices (Sandler *et al.*, 2000). In crystals, a pheromone molecule interacts with diverse amino acids distributed throughout the protein but lining the binding pocket; both hydrophilic and electrostatic interactions are thus presumed to be critical for ligand binding specificity (Sandler *et al.*, 2000; Klusák *et al.*, 2003). It was initially suggested that an α-helix unit at the C-terminus covers the entry to the binding pocket and that this C-terminal α-helix must move to allow pheromone to enter or leave the binding pocket (Sandler *et al.*, 2000). Solution NMR studies suggest that *Bmor*PBP1 exists in two conformations which are pH dependent: a basic form (BmorPBP^B) above pH 6.0 and an acidic form (*Bmor*PBP^A) below pH 4.9 (Damberger *et al.*, 2000). More recent studies suggest that these conformational differences involve the C-terminus: at the higher pH range (i.e., physiological pH) the C-terminus is extended and lies on the surface of the protein (*Bmor*PBP^B) while at the lower pH range this same region forms a seventh α-helix which enters the binding pocket (*Bmor*PBP^A) and displaces a pheromone molecule bound within (Horst *et al.*, 2001). A pH dependent pheromone binding was observed for the *Bmor*PBP1; the pheromone–PBP complex was stable at pH 7.5 but significantly unstable at pH 5.5 (Wojtasek and Leal, 1999a). These studies have suggested that binding of pheromone at the pore tubule and release at the receptor may be driven by local pH differences within the sensillum, pH differences which alter the conformation of the PBP (i.e., from *Bmor*PBP^B to *Bmor*PBP^A) (Wojtasek and Leal, 1999a; Horst *et al.*, 2001; Leal, 2003). The *Bmor*PBP^B conformation would favor binding of pheromone at the pore tubule and transporting it to the OR, while the

*Bmor*PBP[A] conformation would favor releasing pheromone to the OR. The proposed mechanism for such a pH gradient within a sensillum is the neuron membrane. The membrane phospholipids carry a negative charge (at the pH of interest) and are thus presumed to create a locally acidic boundary layer by attracting free hydrogen ions (actually, any cation); the conformation of the PBP–pheromone complex is thus changed from a bound state to a released state as it approaches the membrane (Wojtasek and Leal, 1999a).

Other studies suggest alternative views regarding the mechanisms of odor–OBP binding. The crystal structure of an OBP from the cockroach *Leucophaea maderae* (*Lmad*OBP) has recently been characterized in the presence of either the pheromone component 3-hydroxy-butan-2-one or the fluorescent molecule amino-naphthalen sulfonate (Lartigue *et al*., 2003b). This protein is missing the C-terminal region equivalent to the seventh α-helix in *Bmor*PBP1, and therefore is missing the pH dependent opening/closing mechanism proposed for *Bmor*PBP1 (see above). The binding pocket of the *Lmad*OBP is also more hydrophilic than that of *Bmor*PBP1. The authors suggest that these changes, especially the hydrophilic pocket, may be adaptive (Lartigue *et al*., 2003b), although *Lmad*OBP is overall highly divergent from the other characterized OBPs. The lack of the C-terminal process in *Lmad*OBP is especially interesting and brings to mind the presence/absence of the N-terminal inactivation structure of different voltage-gated ion channels. Clearly it will be helpful to evaluate and compare the structural properties of divergent OBPs from one species, as well as more OBPs from diverse species, in order to determine which features have functional significance and which merely reflect phylogenetic difference.

Some studies also disagree with the pH-conformation hypothesis and to some degree with the crystallographic interpretations. The two PBPs of *L. dispar* show different K_D for the two (+ and −) optical enantiomers of the pheromone (PBP1: $K_D(+)$ 7 μM, $K_D(-)$ 2 μM; PBP2: $K_D(+)$, 1.8 μM, $K_D(-)$, 3 μM) (Plettner *et al*., 2000). However, this binding is not pH dependent over the ranges that would represent near-membrane conditions (pH 7.5 versus pH 5.5) (Kowcun *et al*., 2001). Modeling the membrane influence on the spatial distributions of K^+ and H^+ (i.e., pH) suggests that these influences only come into play at distances well under 2 nm from the cell membrane (Kowcun *et al*., 2001), which itself is only 8 nm thick. These studies suggest that pheromone offloading is not occurring by either pH or ionic strength gradients, but rather suggest that the driving force to offload pheromone is either mass action kinetics (i.e., ORs have higher affinity for pheromone than PBPs) or direct interaction between the pheromone–PBP complex and OR (or perhaps some other membrane protein). These studies also observed an increased PBP binding capacity at high pheromone concentrations, and suggest that the PBP may form dimers dynamically under these conditions to trap pheromone at high concentrations to mitigate against stimulus saturation (Honson *et al*., 2003).

The *Bmor*PBP1 structural studies describe a deep binding pocket with a narrow opening covered by a C-terminal lid, and the involvement of a large numbered amino acids which interact with the majority of the pheromone molecule (Sandler *et al*., 2000; Klusák *et al*., 2003). This seems a highly specific pocket and not terribly amenable to rapid release of pheromone; the conformational changes required would seem to require considerable energy, presumably provided by the proposed pH gradient, the presence of which has yet to be verified (it may be too shallow to have relevance, or it may be buffered by membrane proteins with high isoelectric points and thus be positively charged at pH 7.5). It was observed previously that PBP did not protect pheromone from degradation by a pheromone degrading esterase *in vitro*, though the PBP did maintain aqueous solubility of the pheromone, suggesting that a pheromone–PBP complex had formed (Vogt and Riddiford, 1986a). In contrast, the binding site described for *Bmor*PBP1 would seem well designed for protection from enzymes. The binding site would also seem well designed for a very high degree of specificity, considering the number of interacting amino acid side chains (Klusák *et al*., 2003). Yet studies examining the ability of various pheromone components and fatty acids to displace the fluorescent probe AMA suggest that the binding site may have relatively low specificity for its ligand(s) (Campanacci *et al*., 2001a). So, perhaps the binding site that is being described by crystallography is not the binding site used during rapid pheromone communication. And perhaps, though the PBPs may be conformationally sensitive to pH, these pH environments are not actually experienced *in vivo*. Clearly, one wants a system in which these hypotheses can be experimentally tested. Ideally one wants a genetic model, such as *Drosophila*, where OBPs can be modified or swapped and the result tested physiologically and/or behaviorally.

3.15.4.1.4. Evolutionary genomics of odorant binding proteins The OBP gene family was presumably derived through duplication of a gene with a func-

tion that was likely not chemosensory, and the family has expanded through subsequent gene duplications. Alleles of these duplicated OBP genes accumulated, and evolutionary selection acted on these alleles leading to changes in the properties and functions of the predominant alleles in the species. Speciation events allowed allelic selection to proceed in manners supporting unique olfactory behaviors (life histories) of individual species. Depending on the function (nonchemosensory or chemosensory) of the founder gene(s), subsequent lineages diverged to either chemosensory or nonchemosensory functions. The genes currently listed as OBPs of *D. melanogaster* and *A. gambiae* include sequences with four to twelve cysteines (Hekmat-Scafe *et al.*, 2002), differing significantly from the six cysteines of the gold standard OBPs, differences which assuredly influence the function of these proteins.

Structural relationships between different OBPs can be explored to some extent using phylogenetic analysis tools (**Figure 3**). Such analyses compare amino acid sequences emphasizing similarities and differences. Amino acid sequences are aligned using programs such as ClustalX (Thompson *et al.*, 1997), and trees are constructed using programs such as PAUP (Swofford, 2000) or MEGA (Kumar *et al.*, 2001) and methods such as neighbor joining (Saitou and Nei, 1987) or maximum likelihood (Strimmer and von Haeseler, 1996; Nei and Kumar, 2000) available within these programs. The results of such analyses, when applied to proteins rather than nucleic acids, usually do not imply any evolutionary history, but rather suggest properties (characters) that certain proteins may share. Other criteria must be considered to infer evolutionary relatedness and history such as a demonstrated positive selection (e.g., significant nonsynonymous differences in codon nucleotides) or conservation of gene structure (e.g., exon–intron boundaries, relative positions in chromosomes, identification of neighboring genes: Vogt, 2002; Vogt *et al.*, 2002).

The sequence similarities of most OBPs listed in **Table 2** are summarized in the neighbor joining tree illustrated in **Figure 3**. Overall, these OBPs are highly divergent, indicated by the relatively long lengths of most branches. Several branches include multiple taxa which define specific similarity groups; such groupings may suggest related functions. One such group is the Lepidoptera-specific PBP–GOBP gene family. Other similarity groups include a group of ant OBPs with a reputed role in governing the social behavior of *Solenopsis* spp. (fire ants and their relatives: Ross, 1997; Ross and Keller, 1998; Krieger and Ross, 2002), two groups that include the *Drosophila* OBPs LUSH and OS-E/OS-F, and a group that includes the lepidopteran ABPX proteins. Both the LUSH and ABPX groups include genes belonging to multiple insect orders, a feature that may suggest that these proteins have a functional role common to or of central importance to diverse insects. However, most branches do not include OBPs from multiple orders, suggesting that selection acting on these genes is strongly biased by features unique to the orders, families, or genera represented.

The PBPs and GOBPs of Lepidoptera represent a group that is not present in other insect orders, but these PBPs and GOBPs are clearly only a subgroup of lepidopteran OBPs. Their absence from Diptera, a sister lineage, and the relatively recent emergence of Lepidoptera implied by the fossil record, suggest that the PBP/GOBP genes may have arisen within Lepidoptera, or at least within the lepidopteran/trichopteran lineage (**Figure 4b**). PBPs, GOBP1s, and GOBP2s comprise three distinct subgroups; amino acid sequence identities between PBPs and GOBPs are consistently between 25% and 30%, and amino acid sequence identities between GOBP1s and GOBP2 are consistently about 50%. GOBP1s and GOBP2s are highly conserved (around 90% identical within each group) while PBPs are highly divergent (20% to 95% identical). Also, multiple PBPs have been identified in individual species while only single genes are yet known for GOBP1s and GOBP2s, suggesting that gene duplications are occurring and being retained for PBPs but are either not occurring or not being retained for GOBPs. Clearly, selection is acting very differently on these subgroups, as might be expected for systems supporting reproduction (PBPs) versus general maintenance (i.e., feeding) (GOBPs).

The genes encoding PBP1 and GOBP2 of *M. sexta* (*Msex*PBP1 and *Msex*GOBP2) are adjacent to one another, with coding regions separated by about 2000 bp, and both genes have identical exon–intron structures (Vogt *et al.*, 2002). Proximity and conserved gene structure argue strongly that PBP1 and GOBP2 are derived from a gene duplication, yet the two proteins have very different sequences and temporal and spatial expression patterns. *Msex*PBP1 and *Msex*GOBP2 express in different types of sensilla (**Figure 5a–c**); *Msex*PBP1 expresses only in adult moths while *Msex*GOBP2 expresses in both larvae and adults, but the expression of both is regulated by ecdysteroid hormones (Vogt *et al.*, 1993, 2002). If PBP1 and GOBP2 did derive from a gene duplication, then presumably GOBP1 derived from a subsequent duplication event involving GOBP2. The origins of multiple PBPs are less clear. Multiple PBPs may have been derived from

subsequent duplications involving PBP1, or the PBP1/GOBP2 pair may have been derived from a duplication involving one of these other PBPs. PBP diversification may have been driven by reproductive selective pressures within species, genera, or families (Merrit *et al.*, 1998); however, this does not appear to be the case with the GOBPs which are both highly conserved and broadly distributed among the lepidopteran families. An in-depth comparative study of the PBPs and GOBPs across the Lepidoptera might reveal much of the olfactory evolution of this insect order.

OS-E and OS-F of *Drosophila* are also presumably derived from a gene duplication based on the neighboring relationship of their genes (separated by about 1000 bp), similar exon–intron structure, and similar sequence. However, unlike *Msex*PBP1/*Msex*GOBP2 which differentially express, OS-E and OS-F coexpress in olfactory trichoid sensilla of the *Drosophila* antenna (Hekmat-Scafe *et al.*, 1997); at least a subset of these sensilla contains neurons responsive to the pheromone *cis*-vaccenyl acetate (Clyne *et al.*, 1997). Orthologs of OS-E and OS-F have been tentatively identified in *A. gambiae*, suggesting that the OS-E/OS-F gene duplication preceded the divergence of flies and mosquitoes within the Diptera (Vogt, 2002). A gene with significant sequence similarity to OS-E and OS-F has also been identified in the mosquito *Culex quinquefasciatus* (Ishida *et al.*, 2002b); the sequence conservation of these presumed OS-E/OS-F orthologs among different groups of Diptera suggests their singular importance in the olfactory biology of these species. Unlike in *Drosophila*, the presumptive *A. gambiae* OS-E/OS-F genes are separated by about 30 million nucleotides suggesting that a chromosomal translocation event has occurred. It will be interesting to learn whether this separation has also resulted in a divergence in expression or function between these *A. gambiae* genes.

The PBP/GOBP genes of Lepidoptera and OS-E/OS-F genes of Diptera are just two stories of duplication and expansion of olfactory genes; the previously described pair of *Drosophila* OR genes, Dor22a and Dor22b, are another (Dobritsa *et al.*, 2003) (see Section 3.15.3.1.2). A look at the distribution of OR, OBP, and SNMP homologs on the *Drosophila* chromosomes reveals a rich evolutionary history of gene duplication and translocation in the context of sensory biology and behavioral selection (Vogt, 2003). Increased access to genomes is permitting the identification of gene orthologs and the following of gene change across insect families and orders will allow us to hypothesize function in one species based on the characterized function of a gene ortholog in another.

3.15.4.1.5. Allelic variation of pheromone binding proteins Several efforts have examined allelic variation of PBPs between distinct populations. Electrophoretic variants (possible multiple alleles) were described for both *Apol*PBP1 and *Apol*SE between populations of the moth *A. polyphemus* from New York (Long Island) and Wisconsin. However, this apparent allelic variation appeared high within, but similar between, each population and nothing definitive could be concluded regarding how this variation might affect behavior (Vogt, 1987; Vogt and Prestwich, 1988). LaForest and colleagues (1999) characterized PBP genes from individuals of two populations of the noctuid moth *Agrotis segetum* which use the same pheromone components but in different ratios. However, only neutral sequence variation was observed in the PBP sequences and again nothing definitive could be concluded regarding how such variation might affect pheromone perception and behavior. Similar results were obtained from studies of distinct populations of the European corn borer *Ostrinia nubilalis* (Willett and Harrison, 1999a, 1999b). Positive selection was observed for PBPs of species using different pheromone structures, but it was not clear that this selection resulted from the changes in pheromone components (Willett, 2000a, 2000b). A limitation of all three studies is that each characterized only one PBP; closer examination has demonstrated consistently that lepidopteran species have several PBPs (**Table 2**). It is likely that multiple PBPs derived from relatively recent gene duplications which occurred within specific lepidopteran lineages rather than at the base of the lepidopteran lineage (Merritt *et al.*, 1998). If this is true, then it is also possible that, in certain species, PBP genes did not duplicate or that duplicated genes have become lost. But these possibilities are difficult to assess without a full genome sequence. If functionally relevant positive selection has occurred among the PBPs (which certainly seems likely), it may be discernable only by analyzing the larger repertoire of PBP genes within a species.

3.15.4.2. Odor Transport by OS-Ds, SAPs, or CSPs?

The proteins of another gene family, variously named OS-D, sensory appendage proteins (SAPs), or chemosensory proteins (CSPs), have been suggested frequently to have OBP-like properties in binding and transporting pheromones and other odors within sensilla (reviews: Picimbon, 2003;

Nagnan-Le Meillour and Jacquin-Joly, 2003). These proteins have a wide tissue distribution throughout the body, share no sequence similarity to the OBPs, contain about 100–110 amino acid residues (compared with 140 for OBPs), four conserved cysteines (versus six in OBPs) and six α-helices (similar number but in a very different configuration than OBPs), and a hydrophilic channel that passes through the protein (versus a single-opening pocket in OBPs) (Campanacci *et al*., 2001b, 2001c, 2003; Briand *et al*., 2002; Lartigue *et al*., 2002). **Table 3** lists members of this family reported to date. These proteins are remarkably conserved, showing consistently similar sequence identities independent of the phylogenetic distance of the organisms For example, CSPs share 50–60% identity between the two orthopteran species (*Schistocerca gregaria* and *L. migratoria*), 38–54% identity between the two lepidopteran groups CSPMbra A and CSPMbraB, and 37–50% identity between proteins of the Orthoptera versus Lepidoptera (Jacquin-Joly *et al*., 2001). Such conservation is in stark contrast to the high degree of divergence observed for ORs and OBPs.

Antennal CSPs were first identified through studies searching for antennal-specific genes. In their screen for antennal-specific proteins in *Drosophila*, Carlson's group identified six cDNAs, naming them OS-A through OS-F (McKenna *et al*., 1994). This study yielded OS-E and OS-F, which were among the first OBPs identified outside of Lepidoptera (McKenna *et al*., 1994); one of the non-OBP proteins was named OS-D and was also described that year and named A10 by Pikielny in his characterization of *Drosophila* antennal proteins (Pikielny *et al*., 1994). Two years later, Pelosi's group characterized antennal proteins of several species of phasmid (walking stick), identifying OS-D/A10 homologs in antenna and leg extracts of *Eurycantha calcarata* and *Extatosoma tiaratum* and antenna extracts of *Carausius morosus* (Mameli *et al*., 1996). Another 2 years later, Nagnan-Le Meillour's group reported on the pheromone binding properties of antennal proteins in the moth *M. brassicae* (Bohbot *et al*., 1998), demonstrating nonspecific odor binding to a moth homolog of OS-D/A10 and noting its relationship to the phasmid proteins as well as proteins CLP1 from the labile palps of the moth *Cactoblastis cactorum* (Maleszka and Stange, 1997) and DA6b from the antenna of *A. mellifera* (Danty *et al*., 1998). In 1999, Robertson's group reported their characterization of hundreds of antennal cDNAs of the moth *M. sexta*, including

five OS-D/A10 homologs which they named as sensory appendage proteins (SAPs) (Robertson *et al.*, 1999). In 2000, Pelosi's group characterized five OS-D/A10 homologs from the locust *S. gregaria*, referring to them as chemosensory proteins (CSPs) (Marchese *et al.*, 2000). **Table 3** lists the members of this gene family reported to date.

CSPs associate with a broad range of body tissues, including legs, heads, thorax, antennas, proboscis, subcuticular epithelium, pheromone glands, and ejaculatory duct (Nomura *et al.*, 1992; Dyanov and Dzitoeva, 1995; Nagnan-Le Meillour *et al.*, 2000; Picimbon *et al.*, 2000a, 2001; Jacquin-Joly *et al.*, 2001; Picone *et al.*, 2001; Ban *et al.*, 2003a). CSPs may be absent from the central nervous system (Picimbon *et al.*, 2000b). The name CSP (or SAP) is optimistically biased towards the chemosensory functions of these tissues, though clearly each tissue performs additional functions. Picimbon *et al.* (2000a, 2001) found that CSPs of the moths *B. mori* and *H. virescens* express in antennas, proboscis, legs, thorax, and head. The earliest identified member of the family, P10 of the cockroach *Periplaneta americana*, also expresses in legs, antennas, and heads (Nomura *et al.*, 1992; Kitabayashi *et al.*, 1998). In *H. virescens*, CSP expression in legs is initiated at least 5 days before adult eclosion, during a period when development is still ongoing, and expression persists into adult life; however, this time course does not match that of proteins where specific olfactory association is well established, such as OBPs and SNMP which tend to initiate expression only shortly before adult eclosion (Vogt *et al.*, 1989, 1993; Rogers *et al.*, 1997, 2001b; Picimbon *et al.*, 2001). In the cockroach, P10 expression was primarily associated with leg regeneration (Nomura *et al.*, 1992). While it may be true that most external insect tissues contain chemosensory organs, the mere association of CSPs with these tissues does not necessarily correlate with chemosensory function.

Several CSPs have been shown to associate with chemosensory sensilla, though not in a consistent pattern. In *Drosophila*, OS-D/A10 expression (*in situ* hybridization) was associated with the sacculus, an antennal structure rich in coeloconic sensilla, although actual association with these sensilla was not shown (Pikielny *et al.*, 1994). In the locust *S. gregaria*, antisera to CSPs purified from tarsi reacted with antigen in the lumen of gustatory sensilla of legs, palps, and antennas (Angeli *et al.*, 1999). In the moth *M. brassicae*, CSPMbraA6 expression (*in situ* hybridization) was associated with hair-like olfactory sensilla (trichogen or basiconic) but not with coeloconic sensilla (Jacquin-Joly *et al.*, 2001).

Several ligand binding studies have been reported for these proteins. CSPs from *M. brassicae* have been shown to interact with a wide range of hydrocarbons ranging in length from C9 to C18 and containing a variety of functional groups; K_D values for all of these molecules are close to 1 μM (Bohbot *et al.*, 1998; Jacquin-Joly *et al.*, 2001; Lartigue *et al.*, 2002; Campanacci *et al.*, 2003; Mosbah *et al.*, 2003). CSPs may be capable of receiving multiple ligands within their binding pocket; CSPMbraA6 was shown to bind ligands with a stoichiometry of 3 : 1 (Campanacci *et al.*, 2003). A CSP from the honeybee was shown to interact with C14–C18 compounds, including several compounds reported to be brood pheromones, with K_D values in the 1 μM range (Briand *et al.*, 2002). A broad range of ligands was observed to interact with a CSP from the locust *S. gregaria* in competition studies with the fluorochrome *N*-phenyl-1-naphthylamine; binding of the fluorochrome was heat stable (100 °C, 20 min) and had a K_D of 4 μM, and K_D values of competitors ranged from 10 to 150 μM (Ban *et al.*, 2002, 2003b) (such heat stability in a soluble, globular protein with α-helices and disulfide bonds seems somewhat surprising). CSPs from the wing of the locust *L. migratoria* were purified with the oleoamide bound to the protein, a compound interpreted as an endogenous ligand for this CSP (Ban *et al.*, 2003a); oleoamide is a C_{18} compound used as an industrial lubricant (recombinant PBPs have been isolated bound with spurious fatty acids) (Oldham *et al.*, 2001). Presumably addressing the remarkable lack of discrimination of these proteins, Lartigue *et al.* (2002) wrote "We hypothesize therefore that CSPMbraA6 should interact with membranes to extract pheromones or other lipidic compounds dispersed in the hydrophobic membrane matrix and bring them to their specific target."

It does appear that at least some CSPs associate with chemosensory sensilla, and that they are capable of binding odor-like molecules, if with relatively low selectivity. And their presence in a broad range of insects and tissues together with their small ligand carrying capacity marks them proteins of potentially significant physiological interest. Nevertheless, the importance of these proteins in chemodetection remains remarkably unclear.

3.15.4.3. Pheromone and Odor Degradation by Odor Degrading Enzymes

Signal termination plays a critical role in all chemically mediated biological processes, and this is no

less so in odor detection. The process of pheromone degradation has been studied for some years, at least as far back as Kasang (1971) in *B. mori* and Ferkovich *et al*. (1973a, 1973b) in the cabbage looper moth, *Trichoplusia ni*. Since then, a few pheromone degrading enzymes have been identified and characterized in detail and the general principal of pheromone degradation has become well established. Yet surprisingly little work is being done to investigate odor degrading enzymes (ODEs), in contrast with current efforts on ORs and OBPs. One reason to expand efforts on ODEs is their potential in insect control. If it is true that pheromones are perceived as precise mixtures, then the targeted inhibition of the ODE for a specific component should alter the blend ratio within a sensillum resulting in misperception of the pheromone. Of the three protein classes (ORs, OBPs, and ODEs), ODEs may be the least specific and thus the more generally targetable protein for behavioral inhibition.

ODEs are enzymes selectively evolved to degrade odor molecules (Prestwich, 1987). However, to call an enzyme an ODE it is not enough to merely demonstrate the ability of an enzyme to degrade an odor; that enzyme has to be shown to reside in a space that is relevant to odor detection. This principle should be applied to OBPs and ORs as well. In general, those ODEs studied have been ones that attack specific functional groups, such as acetate esters, aldehydes, alcohols, ketones, and epoxides. ODEs attacking such different functional groups presumably belong to different gene families. The 55 kDa antennal-specific esterase (*Apol*SE) (see Section 3.15.4.3.1.1), that degrades the acetate-ester pheromone component of the silk moth *A. polyphemus* (Vogt and Riddiford, 1981; Vogt *et al*., 1985), is a member of a gene family that encodes insect esterases, an assumption supported by the recent cloning of a candidate *Apol*SE using PCR primers based on conserved regions of insect esterase genes (Ishida and Leal, 2002a). Similarly, the 150 kDa antennal-specific AOXs that degrades the aldehyde components of the *A. polyphemus* and *M. sexta* pheromones (Rybczynski *et al*., 1989, 1990) must belong to a distinct gene family of insect AOXs. So far, only the antennal-specific *Apol*SE and glutathione-*S*-transferase (*Msex*GSTolf) have been cloned (Rogers *et al*., 1999; Ishida and Leal, 2002).

The following section organizes ODEs somewhat artificially into four categories, based on their location in the animal. To some degree this has functional significance, distinguishing between ODEs of the sensillum lumen (soluble or membrane bound), support cell cytosol and body surface.

3.15.4.3.1. Category 1: soluble extracellular ODEs of the sensillum lumen The early studies of the fate of pheromone within the antenna were among the first biochemical studies of insect odor detection. At the time, much seemed to be known about pheromone detection in moths: the pheromone of *B. mori* had been identified and radiolabeled (Butenandt *et al*., 1959; Kasang, 1968); pheromone detection had been characterized by electrophysiology in *B. mori* (Schneider, 1969); the ultrastructure of pheromone sensitive sensilla had been described for *B. mori* (Steinbrecht and Müller, 1971). Adam and Delbrück (1968) had used the *B. mori* pheromone system to justify their "reduction in dimension" hypothesis for ligand-receptor targeting. Steinbrecht and Müller (1971) had suggested that pore tubules might serve as conductive structures for the transport of pheromone molecules from the sensillum surface to receptors of the olfactory neurons (this view was later challenged, by Vogt *et al*. (1985), with the suggestion that OBPs performed odor transport). With this background, a series of studies were performed where radiolabled bombykol was applied to intact male *B. mori* antennas and the products analyzed following solvent extraction. These studies observed the general degradation of the alcohol bombykol to its acid metabolite, but identified no specific enzymes or enzyme activities (Kasang, 1971, 1973; Kasang and Kaissling, 1972; Kasang and Weiss, 1974; Kasang *et al*., 1989a, 1989b). About the same time an independent series of studies examined degradation of the *T. ni* pheromone from the active acetate ester to the inactive alcohol metabolite; these studies demonstrated esterase activities in the antenna but did not identify any antennal-specific enzymes (Ferkovich *et al*., 1973a, 1973b, 1980, 1982; Mayer, 1975; Taylor *et al*., 1981). Although no specific enzymes were identified, these efforts drew attention to the issues of pheromone degradation as an important component of the pheromone detection process.

3.15.4.3.1.1. Antennal-specific esterase The antennal-specific sensilla esterase (SE) of the moth *A. polyphemus* (*Apol*SE) was the first identified pheromone degrading enzyme (Vogt and Riddiford, 1981). The activity of *Apol*SE was visualized on nondenaturing polyacrylamide gel electrophoresis (PAGE), and was shown to be specific to the male antennas and to be located in the sensillar fluid (Vogt and Riddiford, 1981). *Apol*SE molecular mass was estimated at about 55 kDa (Klein, 1987). *Antheraea polyphyemus* was reported to have a two-component pheromone consisting of 9 : 1 ratio of acetate : aldehyde (Kochansky *et al*., 1975).

*Apol*SE was shown to degrade the acetate component and was subsequently purified and subjected to kinetic analysis; a spectrophotometric assay was established using α- and β-naphthyl acetate as substrates, and a radioactive thin-layer chromatography (TLC) assay was established using tritiated pheromone (Vogt *et al.*, 1985). *Apol*SE strongly preferred β- over α-naphthyl acetate, was inhibited by the volatile trifluoroketone 1,1,1-trifluoro-2-tetradecanone ($IC_{50} = 5$ nM), and, most importantly, degraded the sex pheromone with unexpected aggression. By making adjustments for the concentrations and volumes within a sensillum lumen, the *in vivo* half-life of pheromone was conservatively estimated to be 15 ms in the presence of this enzyme. The observation of rapid pheromone degradation prompted the proposal of a new model for pheromone reception, one in which OBPs served as pheromone transporters (replacing pore tubules in that role), and enzymes degraded pheromone molecules to rapidly terminate these odor signals within the sensillum (see **Figures 2 and 8**).

*Apol*SE was used to assess interactions between pheromone and PBP (Vogt and Riddiford, 1986a). *Apol*SE and *Apol*PBP1 were purified from antennas, and the ability of a fixed concentration of *Apol*SE to degrade pheromone was examined in various concentrations of PBP1 and pheromone. ApolSE activity was unaffected under conditions where PBP1 concentrations exceeded pheromone concentrations by 1000 times, suggesting that the PBP did not provide specific protection to pheromone from *Apol*SE, and did not bind pheromone irreversibly. Reduced activity was observed at all pheromone concentrations when PBP1 exceeded 1 μM. It was suggested that this transition was a consequence of protection during binding site-occupancy, but that occupancy must be transient, and that the K_D of the pheromone–PBP interaction must be in the range of 1–10 μM. The activity of *Apol*SE below 1 μM PBP further suggested that pheromone–PBP binding was either very slow or very ephemeral (binding and release occurred rapidly). These conclusions are currently being challenged by alternative views that the pheromone–PBP complex may be quite stable, requiring some secondary interaction to drive dissociation (see earlier discussions regarding OBP function).

An antennal-specific esterase was recently cloned from *A. polyphemus* and tentatively identified as *Apol*SE (accession no. AY091503) (Ishida and Leal, 2002). PCR primers were designed to conserved regions of other known insect esterases, and successfully used to amplify this cDNA. The cDNA encodes a protein with a predicted mass of 59 994 Da (553 amino acids, pI of 6.63) and three potential *N*-glycosylation sites. PCR studies confirmed that mRNA expression is male antenna specific. Kinetic analysis of expressed enzyme and histological localization should confirm the identity of this enzyme, but have not yet been reported. The apparent verification that pheromone degrading esterases are so readily identifiable, and the large number of species utilizing acetate ester pheromones suggest that a door has recently been opened wide for the future characterization of pheromone degrading esterases.

3.15.4.3.1.2. Antennal-specific aldehyde oxidase An antennal-specific aldehyde oxidase (AOX) of the moth *M. sexta* (*Msex*AOX) was the next identified pheromone degrading enzyme (Rybczynski *et al.*, 1989). The activity of *Msex*AOX was visualized on nondenaturing PAGE, and was shown to be antennal specific but present in sensilla of both male and female antennas. *Msex*AOX was observed as a dimer with a combined estimated molecular mass of 295 kDa. *Manduca sexta* uses a multicomponent pheromone consisting exclusively of aldehydes including bombykal (Starratt *et al.*, 1979; Tumlinson *et al.*, 1989, 1994); *Msex*AOX was shown to degrade bombykal to its carboxylic acid, in the absence of any additional cofactors. Both TLC and spectrophotometric assays were established and a variety of substrates and inhibitors were characterized. Making adjustments for the concentrations and volumes within a sensillum lumen, the *in vivo* half-life of pheromone was estimated at 0.6 ms in the presence of this enzyme (Rybczynski *et al.*, 1989).

Many species use pheromone components with chemically diverse functional groups, and thus presumably require multiple ODEs. The pheromone of *A. polyphemus* is a blend of acetate and aldehyde components (Kochansky *et al.*, 1975), and that of *B. mori* is a blend of alcohol and aldehyde (Kasang *et al.*, 1978). Both *A. polyphemus* and *B. mori* have antennal-specific AOXs; both proteins were identified in antennal extracts, and *Apol*AOX was identified in extracts of isolated pheromone sensilla of male antennas (Rybczynski *et al.*, 1990). *Apol*AOX and *Bmor*AOX are both high molecular weight proteins, similar to *Msex*AOX, and are present in male and female antennas. Both *Apol*AOX and *Bmor*AOX can degrade bombykal in the absence of any additional cofactors (Rybczynski *et al.*, 1990). *Bombyx mori* antennas thus contain both alcohol oxidase or dehydrogenase activity (Kasang *et al.*, 1989b) and antennal-specific AOX activities, and

A. polyphemus sensilla contain both antennal-specific SE and AOX activities (Rybczynski *et al.*, 1990). *Apol*SE is only found in male antennas, while *Apol*AOX is abundant in both male and female antennas, suggesting that *Apol*SE was selected to function specifically in pheromone degradation while *Apol*AOX (and presumably *Msex*AOX and *Bmor*AOX) has the multiple functions of inactivating both pheromone and plant volatile odorants (Rybczynski *et al.*, 1990).

Tasayco and Prestwich (1990a, 1990b, 1990c) studied AOX and aldehyde dehydrogenase (ALDH) activities in the antennas of noctuid moths *Heliothis virescens*, *H. subflexa*, and *Helicoverpa zea*. Antennal-specific AOXs were observed in both males and females; molecular weights were similar to those of *M. sexta*, *A. polyphemus*, and *B. mori*. The noctuid enzymes also converted aldehyde pheromone components to their corresponding carboxylic acid without the aid of additional cofactors. Antennnal-specific ALDH enzymes were detected through radiolabeling with a substrate analog, but the location of the enzymes within the antenna was not determined. These ALDH enzymes required the cofactor NAD(P^+). *Apol*SE and *Apol*AOX, as well as the other AOXs described above, function without the assistance of any cofactors, enabling them to act autonomously in the extracellular environment of the sensillum lumen where access to cellular metabolites might be limited. The ALDH requirement for cofactors may suggest that these enzymes are located in the cytoplasm of support cells where cofactors would be available. Antennal ALDH may serve as a biotransformation enzyme for pheromones and possibly xenobiotics in a manner similar to the antennal-specific GST of *M. sexta* (Rogers *et al.*, 1999) (see Section 3.15.4.3.3).

Several studies have reported slow rates of pheromone degradation on antennas (Kasang, 1971, 1974; Kasang and Kaissling, 1972; Kanaujia and Kaissling, 1985; Klun *et al.*, 1991, 1996, 1998). These studies typically applied high concentrations of pheromone to antennas and subsequently extracted metabolites by incubating treated intact antennas in solvent, and analyzed the resulting solvent extract. It is difficult to interpret many of these results as no efforts were made to identify the tissue location of observed enzymatic activity. Enzymes capable of degrading pheromone are present in the cuticle, the cytoplasm of cells, and the hemolymph, in addition to the lumen of sensilla; observed activities may have been from any of these tissue spaces. It was suggested previously that observed slow degradation rates may be due to significant portions of pheromone migrating into the cuticle matrix rather than directly entering sensilla, and that pheromone thus entering the cuticle matrix might exit the cuticle and encounter enzymes at slow rates and thus be degraded at slow rates (Vogt *et al.*, 1985; Vogt, 1987).

3.15.4.3.2. Category 2: membrane-bound ODEs While it might seem most efficient for ODEs to be soluble and evenly distributed throughout the aqueous sensillum lumen, certain classes of enzymes may only be available for selection in membrane-bound forms. Such may be the case with pheromone degrading epoxide hydrolases (EH). The epoxide pheromone disparlure can be degraded by EH activity that is antennal specific and associated with isolated sensilla; this activity is not water soluble, suggesting that it might instead be associated with neuronal or support cell membranes (Prestwich, 1987; Vogt, 1987; Graham and Prestwich, 1992, 1994). Similarly, but in a noninsect system, a membrane-bound ODE that degrades purinergic odor molecules has been characterized in the spiny lobster, *Panulirus argus* (Trapido-Rosenthal *et al.*, 1987, 1990; Grünert and Ache, 1988; Carr *et al.*, 1990; Gleeson *et al.*, 1992). Lobsters, arthropods by all rights, smell many things, including the purines ATP and ADP; the ratio of these molecules is thought to inform the lobster of how recently its food was alive (Zimmer-Faust *et al.*, 1988). Certain olfactory neurons are stimulated by ATP and ADP, and the membranes of these neurons contain enzymes which degrade these purinergic signals (Trapido-Rosenthal *et al.*, 1987, 1990; Gleeson *et al.*, 1992). These enzymes are localized to membrane regions at the base of the sensillum, with their activities oriented towards the lymph cavity.

3.15.4.3.3. Category 3: Cytosolic ODEs – multifunctional ODEs inactivating odors and xenobiotics Olfactory and respiratory tissues of animals are constantly under attack by toxic chemicals from the environment. These xenobiotic compounds have presumably driven the enrichment in such tissues of biotransformation enzymes such as glutathionine-*S*-transferases (GSTs), cytochrome P-450 oxygenases, and UDP-glucuronosyltransferases, and various dehydrogenases and oxidases (reviews: Dahl, 1988; Mannervik and Danielson, 1988; Clark, 1990; Feyereisen, 1999). Many of these enzymes can also attack odor molecules, and this has led to suggestions for mammals that biotransformation molecules may function in odor signal termination (Nef *et al.*, 1989; Lazard *et al.*, 1990, 1991; Burchell, 1991; Ding *et al.*, 1991; Ben-Arie *et al.*, 1993).

Several biotransformation enzymes have been identified in insects. These enzymes have features

suggesting they serve a dual function of attacking both xenobiotics and odor molecules. One of these, *Msex*GSTolf, is an antennal-specific GST in *M. sexta* capable of transforming aldehyde odorants (accession no. AF133268) (Rogers *et al*., 1999). GSTs often function as detoxification enzymes, complexing xenobiotics to endogenous glutathione (a cofactor) and thereby rendering them harmless (Yu, 1983, 1984, 1989; Fournier *et al*., 1992; Snyder *et al*., 1995). Though present in male and female antennas, in male antenna *Msex*GSTolf is restricted to cells underlying the pheromone sensitive trichoid sensilla (**Figure 5a**); this restricted expression to pheromone sensilla suggests that *Msex*GSTolf plays a role in pheromone inactivation (Rogers *et al*., 1999). *Msex*GSTolf mRNA encodes a 219 amino acid protein which lacks an encoded leader sequence; the absence of a leader sequence suggests that GSTolf is not extracellular but rather is retained in the cytoplasm of the cells expressing it. Pheromone molecules entering these cells, perhaps carried by PBPs, would be complexed and inactivated by *Msex*GSTolf and thus prevented from later stimulating the neurons (**Figures 2 and 8**). *Msex*GSTolf shares significant similarity with an antennal GST from *B. mor*i (accession no. AJ006502) (Krieger and Breer, 1998); *Msex*GSTolf and *Bmor*GSTolf are distinct from other insect GSTs and thus may define a unique class of multifunctional biotransformation enzymes (Rogers *et al*., 1999).

An antennal-specific cytochrome P-450 enzyme has been identified in the moth *M. brassicae*; like *Msex*GSTolf, this biotransformation enzyme was also observed to differentially associate with pheromone sensitive trichoid sensilla (accession no. AY063500) (Maïbèche-Coisné *et al*., 2002). Male antennal specific and pheromone degrading P-450 activity has also been observed in the beetle *Phyllopertha diversa*; this activity was membrane-bound, required the cofactor NAD(P)H, and was sensitive to the cytochrome P-450 inhibitors proadifen and metyrapone (Wojtasek and Leal, 1999b). Again, these are presumably enzymes strategically located for the inactivation of xenobiotics, but may have become secondarily selected for pheromone degradation. Discussion earlier in this section described noctuid ALDHs that require cofactors (Tasayco and Prestwich, 1990a, 1990b). This requirement for cofactors in enzymes such as GSTs, P-450s, and ALDHs could be difficult to satisfy in the extracellular space of the sensilla lumen and may therefore suggest a cytosolic location of these enzymes.

A cytosolic location of an ODE may seem incompatible with its function, i.e., once an odor/pheromone passes out of the sensillum lumen and enters a cytoplasm it would seem effectively inactivated and out of reach from the perspective of the ORs. Perhaps this is not so. The restricted association of *Msex*GSTolf or *M. brassicae* P-450 with pheromone sensilla may be the consequence of strong evolutionary selection acting on pheromone systems to maintain low signal backgrounds. Cytosolic signal degradation would ensure that pheromone molecules entering the support cells could not later diffuse back into the sensillum lymph or activate ORs located in the nearby cell bodies of the olfactory neurons, actions that might disrupt reproductive behavior.

3.15.4.3.4. Category 4: cuticular ODEs – surface catabolism of background noise Airborne pheromone and other odors are hydrophobic and tend to adsorb onto the waxy surface of the insect cuticle. Body surfaces thus can collect odors and become sources of background noise if these odors are later released. Degradation of these surface-bound odor molecules might significantly reduce such signal noise.

Pheromone degrading esterase activity associates with the scales covering the outer surface of the silk moth *A. polyphemus* (Vogt and Riddiford, 1986b). Isolated scales were loaded into small cartridges through which volatilized radioactive pheromone was blown ([^{3}H]6*E*,11*Z*-HDA); alcohol metabolites were subsequently extracted indicating that the scales degraded adsorbed pheromone. Isolated scales were suspended in detergent solution containing either α-naphthyl acetate or [^{3}H]-pheromone; both compounds were rapidly degraded. The degradative activity was apparently cross-linked to the scale cuticle as removal of the scales from the incubation solution reversibly removed the enzymatic activity as well. Boiling scales had only a partial effect on diminishing enzyme activity, suggesting that the presumed enzyme might be structurally stabilized by cross-linking to the cuticle. Activity was inhibited by trifluoroketone 1,1,1-trifluoro-2-tetradecanone and *O*-ethyl *S*-phenyl phosphoramidothiolate (EPPAT), the same compounds that inhibited the pheromone degrading of *Apol*SE (Vogt *et al*., 1985). Scales isolated from different body surfaces of *A. polyphemus* had somewhat different activities, and scales taken from other Lepidoptera had little or no activity compared to *A. polyphemus*, suggesting the activity was species specific for the *A. polyphemus* pheromone. These data suggested that the activity represented an essentially solid state and fairly indestructible enzyme selected to degrade sex pheromone adsorbed to the body surface, and that the *A. polyphemus* activity was

tuned to the *A. polyphemus* pheromone (assuming the other species tested had their own scale esterases). This enzyme may function to reduce the noise that adsorbed pheromone might create if later released at an inappropriate moment.

Surface catabolism of pheromones has been observed anecdotally but rarely studied with passion. Several studies have shown that homogenates or sonicates of general body parts of moths will degrade pheromone (Kasang, 1971; Mayer, 1975; Ferkovich *et al.*, 1982). Kasang (1971) suggesting that this activity was due to surface enzymes acting to prevent adsorbed pheromone serving as a false signal source. Ferkovich *et al.* (1982) suggested that activity associated with legs of *T. ni* might serve to clean the antennas of residual pheromone by using the legs as antennal combs. Catabolism of a beetle pheromone, for example, has been observed by placing beetles elytra vials containing volatilized radioactive pheromone. Such enzymes should be of interest as solid state enzymes in applications of non-solution chemistry or air filtration/detoxification. But they should also be interesting as examples of bizarre adaptive biochemistry underlying pheromone based behavior.

3.15.4.3.5. Inhibition of ODEs to inhibit pheromone behavior If ODEs can be differentially inhibited, then pheromone blend ratios might be altered within the sensillum and the pheromone thus misperceived and rendered unattractive. Several studies have used volatile trifluoroketones (TFKs) to probe the physiological and behavioral responses to lepidopteran pheromones; a TFK was shown to be a potent inhibitor of *Apol*SE (Vogt *et al.*, 1985). These studies have produced variable results. A TFK applied directly to the antennas of the pyralid moth *O. nubilalis* partially inhibited whole antennal esterase activity but had no significant effect on male attraction to a pheromone source in a wind tunnel (Klun *et al.*, 1991). However, attractant behavior was clearly inhibited in wind tunnel assays following pretreatment of the processionary moth (*Thaumetopoea pityocampa*) to volatilized TFKs (Quero *et al.*, 1995), direct application of TFKs to the antennas of the noctuid moths *Spodoptera littoralis* and *Sesamia nonagrioides* (Bau *et al.*, 1999), or copresentation with pheromone on a lure for the noctuid moth *M. brassicae* (Renou *et al.*, 1999). The effectiveness of TFKs seems to relate to their structural similarity to the pheromone (Renou and Guerrero, 2000); copresentation of TFK and pheromone in field studies significantly reduced the attraction to traps for *S. nonagrioides* (Riba *et al.*, 2001). The exact mode of action of TFKs is not clear; while they can clearly inhibit esterase activities (Vogt *et al.*, 1985; Vogt and Riddiford, 1986b), they may also interact with ORs (Klun *et al.*, 1991; Pophof 1998; Pophof *et al.*, 2000), and OBPs (untested).

3.15.4.4. Sensory Neuron Membrane Proteins

Sensory neuron membrane proteins (SNMPs) are antennal-specific proteins of Lepidoptera expressed in olfactory neurons and located in the receptive membranes of the dendrites (**Figures 5f and 6**). SNMPs belong to a larger gene family (CD36) that includes identified genes in other insects and other phyla (see below). SNMP (SNMP1) was first identified in the moth *A. polyphemus* (Rogers *et al.*, 1997), and subsequently in the moths *B. mori*, *H. virescens*, and *M. sexta* (Rogers *et al.*, 2001b); a second SNMP (SNMP2) was also identified in *M. sexta* (Robertson *et al.*, 1999; Rogers *et al.*, 2001b). These proteins express in both male and female antennas, although they are more abundant in male antennas, at least in *A. polyphemus* and *M. sexta* (not determined in *B. mori* or *H. virescens*). SNMPs are about 520 amino acids long; *Apol*SNMP1 is expressed as a 59 kDa peptide that is apparently posttranslationally modified to 69 kDa (Rogers *et al.*, 1997, 2001b). The proteins are thought to contain two presumptive transmembrane domains located near the C- and N-terminals and a single large extracellular loop which contains several *N*-glycosylation groups and presumed disulfide bridges (Rogers *et al.*, 1997, 2001b; Rasmussen *et al.*, 1998; Tabuchi *et al.*, 2000). The amino acid sequence identities between each SNMP1 range from 67% to 73%, and the identities between *Msex*SNMP2 and any of the SNMP1s are about 25%. Both SNMP1 and SNMP2 were recently identified in *M. brassicae* (*Mbra*SNMP1 accession no. AF462066); *Mbra*SNMP2 and *Msex* SNMP2 are about 65% identical (Jacquin-Joly, personal communication).

SNMP expression suggests these proteins play a central role in odor detection. *Apol*SNMP1, *Msex*SNMP1, *Msex*SNMP2, and *Bmor*SNMP1 are all known to be antennal specific (Rogers *et al.*, 1997, 2001b). *Apol*SNMP1, *Msex*SNMP1, *Msex*SNMP2, and *Hvir*SNMP1 are all known to express in olfactory neurons, and *Apol*SNMP1 protein has been visualized in the receptor membranes of these neurons (Rogers *et al.*, 1997, 2001a, 2001b; Krieger *et al.*, 2002) (**Figure 5**). *Apol*SNMP1 and *Msex*SNMP1 have been shown to be expressed late in adult development and into adult life, after morphogenesis has been completed but coincident with the expression of *M. sexta* OBPs and AOX and the onset of olfactory function (Vogt *et al.*, 1993;

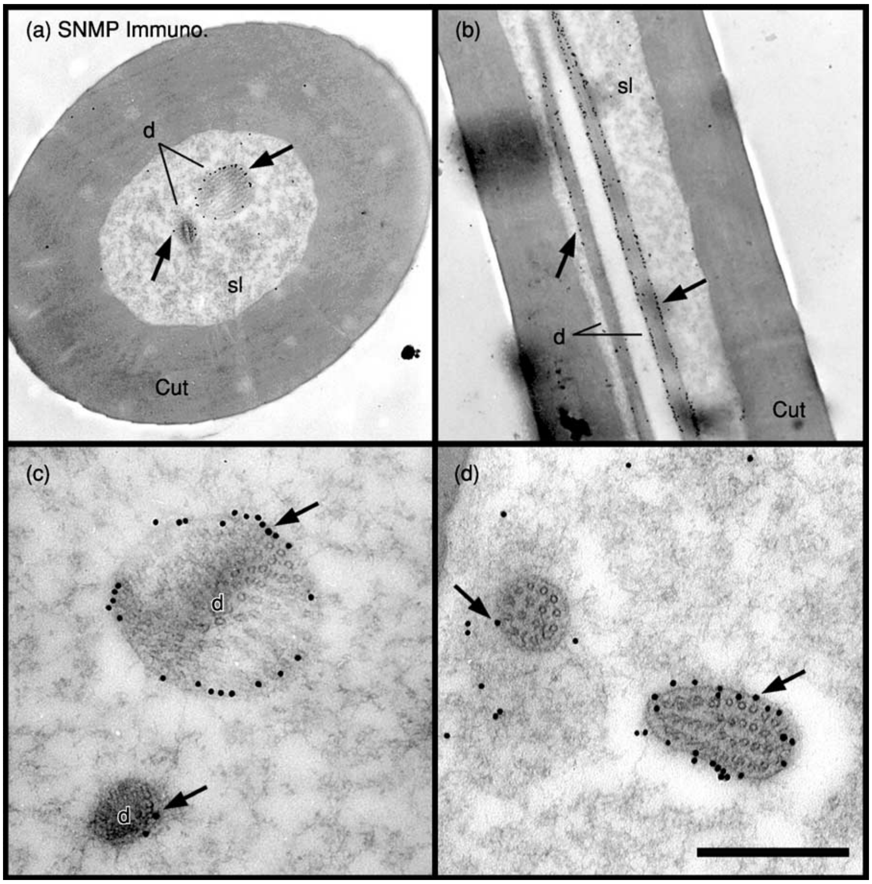

Figure 6 SNMP immunolabeling of electron micrograph sections of pheromone-sensitive trichoid sensilla. SNMP antibodies were visualized using secondary antibody conjugated to 10 nm colloidal gold particles. (a) and (b) include sensillum cuticle; (c) and (d) show only dendrites. Sensilla contained two neurons; one neuron consistently showed significantly greater labeling. Scale bars: (a) 1.25 µm, (b) 2.5 µm (c, d) 0.5 µm. (Modified from Rogers, M.E., Steinbrecht, R.A., Vogt, R.G., **2001a**. Expression of SNMP-1 in olfactory neurons and sensilla of male and female antennas of the silkmoth *Antheraea polyphemus*. *Cell Tissue Res. 303*, 433–446.)

Schweitzer *et al*., 1976; Rogers *et al*., 1997, 2001b). *Hvir*SNMP1 expression coincides with the expression of OR genes in adult male *H. virescens* (Krieger *et al*., 2002). The unique and abundant association of SNMPs with the receptor membrane of olfactory neurons at a time when these neurons are capable of detecting and responding to odors suggests that SNMP are involved in odor detection.

What do SNMPs do? The identification of *Apol*SNMP1 followed photoaffinity labeling studies that tentatively identified a 69 kDa protein as a pheromone receptor (Vogt *et al*., 1988) (**Figure 5f**); however, a role as pheromone receptor seems highly unlikely because SNMPs appear to associate with most olfactory neurons, and are neither 7-transmembrane domain receptors nor show the diversity expected for ORs. SNMPs certainly show no similarity to the presumed ORs identified in *D. melangaster*, *A. gambiae* and *H. virescens* (Clyne *et al*., 1999; Vosshall *et al*., 1999; Hill *et al*., 2002; Krieger *et al*., 2002). If SNMPs are not ORs, what are they?

SNMPs are homologous to a family of receptor proteins characterized by the human fatty acid transporter (FAT) CD36 (Oquendo *et al*., 1989; Greenwalt *et al*., 1992; Abumrad *et al*., 1993; see also Rogers *et al*., 2001a) (**Figure 7**). Among vertebrates, the CD36 family includes proteins known as scavenger receptors including LIMP II (Vega *et al*., 1991; Sandoval *et al*., 2000; Tabuchi *et al*., 2000), SRB1 (Acton *et al*., 1994, 1996; Krieger, 1999), and CLA 1 (Calvo and Vega, 1993). Members of this family have also been characterized in the insect *D. melanogaster* (Hart and Wilcox, 1993; Franc *et al*., 1999; Kiefer *et al*., 2002) and the slime mold *Dictyostelium discoideum* (Karakesisoglou *et al*., 1999; Janssen *et al*., 2001; Janssen and Schleicher, 2001).

The function of the vertebrate CD36 proteins is becoming clear. In mammals, these proteins are reported to be receptors for both high and low density lipoproteins (HDLs and LDLs), transporters of cholesterol and phospholipids, thrombospondin receptors, and cell recognition receptors for phago-

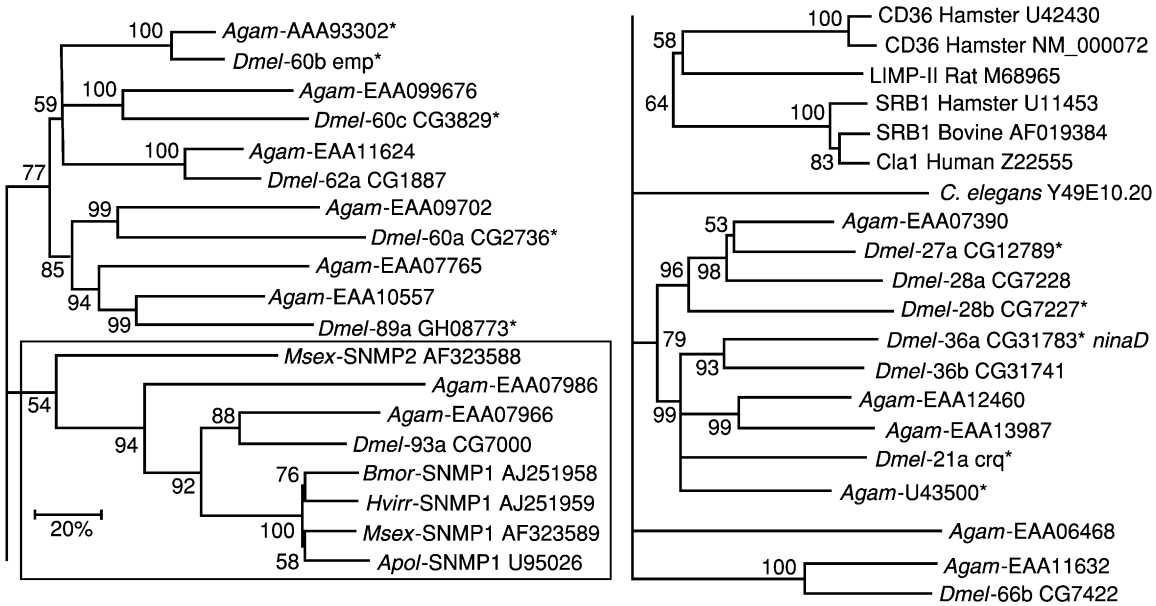

Figure 7 A neighbor-joining tree including lepidopteran SNMPs and their homolog in the *Drosophila melanogaster* and *Anopheles gambiae* genomes, as well as representative homolog from vertebrates (mammals) and a nematode (*Caenorhabditis elegans*). Box surrounds a similarity group that includes the olfactory specific lepidopteran SNMPs; *Dmel*-CG7000 is also known to be antennal specific (Vosshall, personal communication). Branches are collapsed to 50% bootstrap value or greater, based on 1000 replicates.

cytosis and recognition of *Plasmodium* (malaria) infected erythrocytes. Its role in malaria response was the first property ascribed to CD36 (Oquendo *et al.*, 1989); CD36 is expressed in endothelial cells of blood vessels and is responsible for cytoadherence of infected erythrocytes to these endothelial cells (Gamain *et al.*, 2002; Udomsangpetch *et al.*, 2002). But the role of these proteins most studied is their involvement in heart disease, and specifically the formation of vascular plaques in atherosclerosis. Plaque formation involves lipid/cholesterol uptake by macrophages; this uptake converts the macrophages to foam cells; both cell phenotypes secrete growth factors which stimulate the formation of plaques. CD36 and SRB1 are expressed in these macrophages and are responsible for the binding of HDLs and LDLs to the macrophage, as well as the transport of cholesterols (components of the HDLs and LDLs) both into and out of the macrophage, either by forming channels (Calvo *et al.*, 1998; Gu *et al.*, 1998; Coburn *et al.*, 2001; Reaven *et al.*, 2001; Frank *et al.*, 2002; Ibrahimi and Abumrad, 2002; Liu and Krieger, 2002; Miyazaki *et al.*, 2002; Moore *et al.*, 2002; Podrez *et al.*, 2002a, 2002b; Tsukamoto *et al.*, 2002; Kuniyasu *et al.*, 2002) or by endocytosis (e.g., Kuniyasu *et al.*, 2003). Similar activities of these proteins are now being examined in other contexts, including the mammalian nervous system with possible involvement in the mediation of microglial and macrophage responses to β-amyloid, playing roles in proinflammatory events associated with Alzheimer's disease (e.g., Panzenboeck *et al.*, 2002; El Khoury *et al.*, 2003; Srivastava, 2003). So, members of the vertebrate CD36 family can bind protein–lipid complexes and transport lipids across the cell membrane. These proteins have other less studied functions and activities as well. CD36 is involved in cytoadhesion and phagocytosis of rod outer segments in the eye (Ryeom *et al.*, 1996). LIMP II has some as yet unknown function in lysosomes (Kuronita *et al.*, 2002). SRB1 has recently been implicated as a receptor for hepatitis C virus (Scarselli *et al.*, 2002).

About 14 SNMP/CD36 homologs are present in the genomes of both *Drosophila melanogaster* and *A. gambiae* (Figure 7). Three of the *D. melanogaster* proteins have been characterized: emp (Hart and Wilcox, 1993), Croquemort (Franc *et al.*, 1996, 1999; Lee and Baehrecke, 2001), and the product of *ninaD* (CG31783) (Kiefer *et al.*, 2002). Emp (epithelial membrane protein) expresses in ectodermally derived tissues in the embryo and larva, including epithelial cells of wing imaginal discs; the authors suggested emp might have a role in development, but little more is known about this protein (Hart and Wilcox, 1993). Croquemort (Crq, catcher of death) expresses in circulating macrophages which engulf apoptotic cells by phagocytosis during

nonautophagic cell death; Crq serves, perhaps along with other receptors, to mediate this process (Franc *et al*., 1996, 1999; Lee and Baehrecke, 2001). Although the precise role of Crq in this process is not known, the similarity between this activity and the phagocytosis activity of CD36 in mammals suggests that functions of this gene family are conserved between these two distant phyla (Ryeom *et al*., 1996; Franc *et al*., 1999). *ninaD* is a blind mutant that is deficient in the dietary uptake of the visual pigment precursor carotenoids; the *ninaD* mutation is in the gene CG31783, a CD36 homolog; *P*-element mediated transformation with wild-type CG31783 rescues *ninaD* mutants (Kiefer *et al*., 2002). NinaD expression was detected in embryonic midgut primordia, in mesodermal tissue giving rise to hemocytes and macrophage, and in hemocytes. The authors suggest that NinaD functions in the uptake of carotenoids, in a manner similar to the uptake of cholesterol and phospholipids by mammalian CD36 and SRB1 proteins (Frank *et al*., 2002; Liu and Krieger, 2002).

The lepidopteran SNMPs are the only CD36 homologs clearly identified so far in neurons. Given what is known about the anatomy and physiology of olfactory sensilla (Steinbrecht, 1999), it is difficult to translate the specific described activities of the mammalian and dipteran members of the CD36 gene family to olfactory function. However, in a general sense, members of this gene family function as receptors in cell–cell interaction, as receptors that bind protein–lipid complexes, and as transporters of small hydrophobic molecules such as cholesterol and probably carotenoids. Translating these activities into olfactory activities to formulate hypotheses of SNMP function is feasible (**Figure 8**). One *Drosophila* and two *A. gambiae* proteins share notable sequence similarity with the lepidopteran SNMPs (**Figure 6**), and it may prove that studies of these dipteran proteins, and especially CG7000 of *Drosophila*, may prove fruitful in elucidating SNMP function.

3.15.4.5. Perireceptor Models

Figure 8 illustrates several versions of the perireception scheme presented earlier (**Figure 2**) and redrawn in **Figure 8a**. In these schemes, OBPs transport odors to receptors and ODEs degrade odors where and when they have the opportunity. A major concern regarding OBP function is the

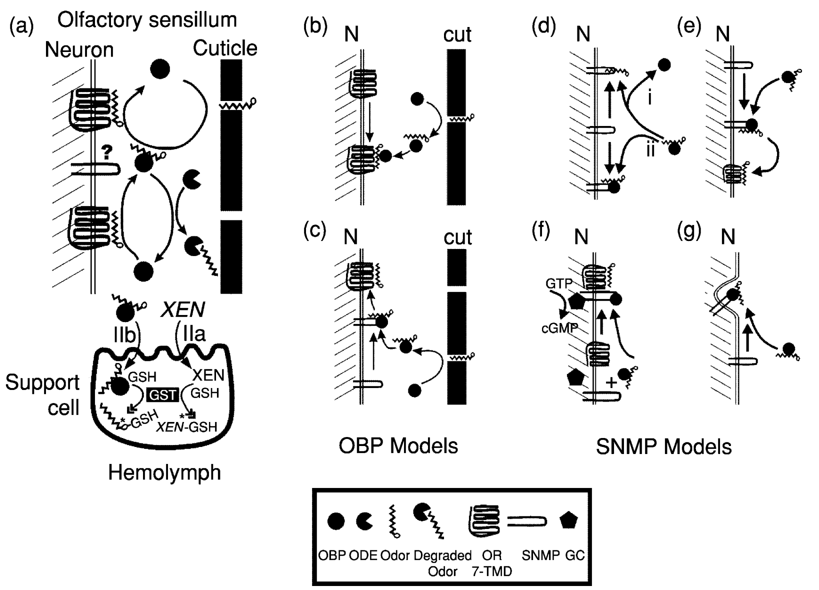

Figure 8 Models of ODE, OBP, and SNMP activities. (a) Depicts the general model for OBP and ODE activities proposed by Vogt *et al.* (1985); support cell activity is based on Rogers *et al.* (1999). Odor molecules are transported to ORs by OBPs and degraded by ODEs; odor molecules entering support cells are inactivated by dual function enzymes such as GSTs which also attack xenobiotics. (b) and (c) suggest alternative schemes for OBP activity (from Vogt *et al.*, 1999), where the ORs are stimulated by a stable odor–OBP complex (b), or by free odor after the odor–OBP complex is destabilized by some other process such as interaction with SNMP (c) or cell membrane (Wojtasek and Leal, 1999a). (d–g) Several possible functions for SNMP (from Rogers *et al.*, 2001a). SNMP may act as a novel odor receptor for either free odor (d-i) or odor–OBP complex (d-ii); or may destabilize the odor–OBP complex freeing odor to interact directly with ORs (e). Alternatively, SNMP may complex with ORs or cytosolic proteins to contribute in some manner to odor reception (f) or serve as an internalization process bringing odor or odor–OBP complexes into the cell (g). Further details on these models can be read in Rogers *et al.* (2001a, 2001b), and are discussed in the text.

reversibility of binding within a physiologically relevant period of time (10–500 ms); thus, receptor activation is represented as either a simple transfer of pheromone from OBP to OR (**Figure 8a**), involving the direct interaction of a odor–OBP complex (**Figure 8b**) or following destabilization of the odor–OBP complex mediated through interactions with the membrane or other membrane proteins such as SNMP or some OR partner such as Dor83b (**Figure 8c**). Some of these alternatives have been considered in a mathematical model developed by Kaissling (e.g., Kaissling, 2001).

Several schemes for SNMP action are shown in **Figure 8d–g**. **Figure 8d** considers the unlikely scheme that SNMP functions as an odor receptor, binding either (1) free odor or (2) the odor–OBP complex, while **Figure 8e** considers SNMP as a destabilizer of the odor–OBP complex. Perhaps more interesting is the scheme considered in **Figure 8f** where SNMP interacts with the OR or with intracelluar proteins (perhaps a guanylate cyclase, as described by Simpson *et al.* (1999)), or in some context similar to heterodimer receptor interactions observed in other systems (Vosshall and Keller, 2003). Finally, **Figure 8g** considers that SNMP might function to internalize odors or odor–OBP complexes, perhaps functioning as part of a signal termination pathway that removes odor accumulating near the membranes and thus maintains a concentration gradient for odors towards the neurons. This would be similar to the carotenoid transport function of NinaD in *Drosophila*, or the cholesterol transport function CD36 and SRB1 in mammals (Frank *et al.*, 2002; Kiefer *et al.*, 2002; Liu and Krieger, 2002; Kuniyasu *et al.*, 2003). Not shown is the possibility that SNMP1 and SNMP2 serve as phenotype determinants of the respective neurons, providing a communication link between the sensilla neurons (cell–cell interaction) that sustains the identity of the respective neurons. These schemes are described in greater detail in Rogers *et al.* (2001a).

3.15.5. Conclusions

3.15.5.1. Does the Detection of Pheromones Differ from the Detection of Other Odor Molecules?

For many years, detection of pheromones was viewed as a unique system, distinct from the detection of odor molecules. However, pheromones are odor molecules, and the detection of pheromone at the level of the sensillum (i.e., periphery) appears to be an adaptationally selected version of the detection of odors in general. Similarly, the central processing of pheromone and other odor signals has been argued to represent variations on a common theme (Christensen and Hildebrand, 2002). Nearly all of the elements illustrated in **Figure 2** have homologs identified in both pheromonal and nonpheromonal systems. OBPs have been identified in orthopteroid and holometabolous/hemipteran lineages suggesting they are present at least throughout the neopterous insects, though their rare encounter in orthopteroid insects suggests they may have expanded considerably in the holometabolous lineages. One lineage of OBP, the PBPs and GOBPs, appears to be specific to the Lepidoptera and represents by far the most abundant OBPs present in lepidopteran antennas despite evidence that there are many more OBP genes expressed in the antennas (Vogt *et al.*, 1991a; Robertson *et al.*, 1999). Pheromone-specific lineages of OBP genes may also exist in other species, as suggested by distinct PBP/OBP lineages in beetle (**Figure 3**). ODEs have also been identified associating with both pheromone and nonpheromone sensilla, though there is clearly an enhancement in these enzymes in pheromone sensilla, at least in the Lepidoptera. ORs so far identified are yet to be associated with pheromone ligands, but the transduction pathway illustrated in **Figure 2c** has been shown to support both pheromone and nonpheromonal transduction in insects spanning the neopteran lineages. Pheromone ORs may yet prove to be derived (distinct in sequence and structure) from other ORs, but they are strongly predicted to be GPCRs activating and to be activated by similar transduction and perireceptor pathways as the nonpheromone ORs that have been characterized in *Drosophila*. It therefore seems appropriate now to do away with the old distinction of specialist (ligand equals pheromone) and generalist (ligand equals plant volatile) olfactory receptors (i.e., sensilla and OSNs) and instead focus on the commonalities of these systems and how the various pathways have become selected to detect and pass on sensory information in the context of life history needs of the species.

3.15.5.2. Are OBPs Necessary for OR Activation?

The behavioral response to ethanol of the *Drosophila lush* mutant has been considered as a strong support for a critical role for OBPs in odor detection (Kim *et al.*, 1998; Kim and Smith, 2001). Assuming that Lush functions to transport ethanol to ORs, these experiments suggest OBPs are important in odor detection, but do not distinguish between (1) transport and (2) OBP–OR interaction. Certain-

ly, odor detection will be influenced by the effectiveness of any system delivering odor molecules to the ORs, and the diversity and selectivity of OBPs seems to suit them to this role. However, several studies have suggested, or at least considered the possibility, that the odor–OBP complex functions as an intact unit in stimulating ORs (Prestwich *et al.*, 1995; Ziegelberger, 1995; Plettner *et al.*, 2000; Kowcun *et al.*, 2001). Odor–OBP–OR interaction implies a high degree of stability in the odor–OBP complex, a view supported by several recent studies (Wojtasek and Leal, 1999a; Damberger *et al.*, 2000; Sandler *et al.*, 2000; Leal, 2003). Lazar *et al.* (2002) have gone so far as to suggest that such stability of the odor–OBP complex argues that OBPs are not deliverers of ligand (i.e., transporters), but rather are sequesters of ligand (inactivators), although this conjecture was based on a rather extreme extrapolation from elephant OBPs to moth OBPs, systems which share no homology in gene or species (beyond a divergence in their phylogenetic lineages perhaps at least 1 billion years ago) (Fortey *et al.*, 1997; Erwin and Davidson, 2002).

Several studies suggest OBPs may not be directly required for OR activation. In one study, olfactory neurons grown in primary culture responded to pheromone in the absence of applied PBP (Stengl *et al.*, 1992). These cultures were established by dissociating cells of an early developmental stage of adult male antennas of the moth *M. sexta*. The authors questioned the necessity of PBPs in pheromone transduction, but also observed that PBP secreting cells may have been present and that PBP thus may have been present in the culture. However, under somewhat analogous conditions, *Drosophila* OR Dor43a was expressed in frog oocytes and stimulated with applied odors (Wetzel *et al.*, 2001). These experiments were done without any applied OBP, and in the absence of any cells that could express an OBP, suggesting that the odor–OR interaction did not require a specific interaction with OBP. In a third study, the *Drosophila* OR Dor43a was misexpressed in olfactory sensilla lacking their endogenous ORs Dor22a/Dor22b (Dobritsa *et al.*, 2003). Neurons of Dor22a/Dor22b sensilla responded to Dor47a odor molecules, suggesting that the endogenous Dor22a/Dor22b OBP(s) was capable of transporting the Dor47a ligand. If Dor22a/Dor22b and Dor47a sensilla express different OBPs, which is not currently known, then presumably if the Dor22a/Dor22b OBP was transporting the Dor47a ligand, it was doing so without a high degree of specificity. Also, if OBP–OR interactions do occur, this experiment suggests they do not occur with a high degree of specificity. However, as there are as yet no correlations between the coexpression of ORs and OBPs, it remains possible that the Dor22a/Dor22b and Dor47a OBPs are the same, and that these assumptions are not supported.

3.15.5.3. Regulation of Pheromone Detection by Hormones, and the Regulation of Hormones by Pheromones

This subject falls into two broad areas: the hormonal regulation of olfactory development and gene expression, and the hormonal regulation of olfactory activity. Neither area has been heavily explored in insect olfactory systems, but sufficient work has been carried out to suggest there is much here to be studied. One can expect that development of the embryonic/larval olfactory system, modifications to the olfactory systems of hemimetabolous insects in the ultimate molt from juvenile to feeding adult, and metamorphosis of the olfactory systems of holometabolous insects offer rich landscapes to explore in an otherwise well-established background of endocrine studies (Truman and Riddiford, 2002). It is known that expression of the moth *M. sexta* PBP1, GOBP1, and GOBP2 are induced by declining levels of ecdysteroids late in adult development (Vogt *et al.*, 1993) and that *Msex*GOBP2 expression is turned off and on again during a larval molt as if it were being regulated by ecdysteroids (Vogt *et al.*, 2002). And it is known that several other olfactory genes including *MsexAOX*, *MsexGSTolf*, and *MsexSNMP1* turn on coincident with the *M. sexta* OBPs, suggesting they too may be under ecdysteroid regulation (Rybczynski *et al.*, 1990; Rogers *et al.*, 1999, 2001b). We also know that eversion of the *M. sexta* antennal imaginal disc during the fifth larval instar is ecdysteroid sensitive (Fernandez and Vogt, unpublished data) as is the proliferation of antennal sensory cells shortly after pupation and early during adult development (M.D. Franco and R.G. Vogt, unpublished data). These studies verify that the ecdysteroid (and juvenile hormone) regulation of olfactory development offer significant research opportunities.

The hormonal regulation of olfactory activity is largely unexplored territory. Insects display strong circadian behavioral shifts; moths, for example, have long been known to display sex pheromone-related behaviors at night (Fabre, 1916; Rau and Rau, 1929) (see **Chapter 3.11**). While it is well established in Lepidoptera that pheromone release and pheromone associated behaviors are strongly regulated in a circadian fashion, there are no reports of circadian changes in the OSN response to sex pheromones. There is, however, a study in *Drosophila* demonstrating circadian changes in the antennal

response to several odor molecules, though the function for this is only speculated to relate to feeding ecology (Krishnan *et al.*, 1999; also discussed by Zwiebel, 2003). There is also recent data from *A. gambiae* about changes in the expression of a number of olfactory-related gene products following a blood meal (Justice *et al.*, 2003). While these responses may be under local control, they may also be subject to endocrine pathways. Interestingly, the antenna, like most insect appendages, has a pulsatile organ at its base to move hemolymph through the antenna (Pass, 2000). In some insects at least, this also serves as neurohemal organ; hormones released from neurosecretory cells terminating in this structure are sent directly to the antenna, presumably to act in some as yet unknown fashion on antennal cells (Beattie, 1976; Pass *et al.*, 1988a, 1988b; Pass, 2000). Hormones can certainly come from other sources in the insect, but this proximity of neurosecretory cells relative to the antenna seems a strong, if indirect, suggestion that the olfactory activities are under hormonal regulation.

Pheromones have been categorized as releasers, stimulating or modulating an immediate behavioral response, and as primers, stimulating or modulating a longer-lasting physiological state (Wyatt, 2003). The best-characterized releaser pheromones may be the attractant sex pheromones of Lepidoptera which modulate visually guided flight of male moths (Kennedy *et al.*, 1980; David *et al.*, 1983; Preiss and Kramer, 1983; Willis and Arbas, 1991; Vickers *et al.*, 2001; Baker, 2002; review: Schneider, 1992). Primer pheromones regulate behavioral and developmental states in social insects (Vander Meer *et al.*, 1998) *Leptinotarsa decemlineata* (see **Chapter 3.13**). Pheromones may serve both categories, such as a male pheromone of the Colorado potato beetle, which serves as a female attractant (releaser), but may also modulate male pheromone production through an endocrine pathway (primer) (Dickens *et al.*, 2002). Activities of releaser pheromones are presumably mediated through the interaction of pheromone-sensitive neural pathways with other sensory pathways to modulate motor output (Olberg, 1983; Kanzaki and Shibuya, 1986; Olberg and Willis, 1990, Kanzaki *et al.*, 1991; Vickers and Baker, 1994; Kanzaki and Mishima, 1996; Kanzaki, 1998; Mishima and Kanzaki, 1998, 1999; Lei *et al.*, 2001).

Activities of primer pheromones are presumably mediated through the endocrine system. Unfortunately, there is currently no established neural, molecular, or genetic pathway between specific olfactory sensilla/OSNs/pheromones and any endocrine pathway. Nevertheless, this is a relatively easy pathway upon which to speculate. Neuroendocrine cells are distributed throughout the insect brain (Nässel, 2002), and projection neurons from the olfactory lobes arborize in regions rich in these cells (**Figure 1**); certainly the opportunity for olfactory-based signaling to influence the release of neurosecretory hormones is considerable. Given the state of genetically driven cell markers (Wong *et al.*, 2002), all that may be lacking is a well-established pheromone responsive OR and the knowledge of the specific hormone(s) that pheromone simulates in order to establish such a neural pathway.

New technologies drive the acquisition of new knowledge. Publicly accessible computer databases, N-terminal sequencing, cDNA cloning, PCR, and structural and spectroscopic biochemistry have generated much of the information presented here. The last few years have seen *Drosophila* emerge as a major tool in olfactory research, both because of its manipulatable genetics and its recently sequenced genome. The coming years will no doubt see these technologies spread to other insect models and the applications of profound new technologies to present models (Kalidas and Smith, 2002; Mori, 2002; Tomita *et al.*, 2003). Changing technologies not only provide changes in research approaches, but also change that laboratories and which intellectual assets are serving as the central players of the moment. But for all this, insect olfaction is an inherently biological phenomenon. The vast number of insect species with their divergent families of olfactory genes that serve to translate key environmental information supporting individual life histories and behavior makes insect olfaction a unique system in which to study the organization, actions, and evolution of genes and genetic pathways in an ecological context. At the conferences, it is the rule rather than the exception to hear cutting edge presentations on gene and protein structure and properties, on gene regulation, expression, and function, on olfactory neural circuitry, coding and behavior, on the most superb neural anatomy, on development at all levels, on the chemistry of pheromone production and the evolution of pheromone production and detection, on ecology of odor detection, on field application of pheromones and crop protection using pheromones, and recently, on remote sensing and military defense. Perhaps more than any other area of biology, insect olfaction is a system offering and generating enormous intellectual integration. For this aging scientist, studying insect olfaction has been highly stimulating, and I can only envy those younger scientists now embarking in this field.

3.16 Endocrinology of Crustacea and Chelicerata

E S Chang, University of California, Bodega Bay, CA, USA
W R Kaufman, University of Alberta, Edmonton, AB, Canada

3.16.1. General Introduction

The Arthropoda comprise four subphyla (Mitchell *et al.*, 1988): Trilobita (about 4000 extinct species), Crustacea (about 40 000 species), Uniramia (about 1 million species, most of them insects), and Chelicerata (about 65 000 extant species). Although the focus of this series is on the insects, the editors of this volume decided that any thorough treatment of insect endocrinology should include a comparative discussion of the hormones of the other major extant arthropod groups.

Some of the hormones described here are ubiquitous among the Arthropoda (e.g., the ecdysteroids). There are several other hormones, however, that appear to be unique in these groups. Of course these groups cannot be treated as comprehensively in a single chapter as can the insects in an entire volume.

3.16.2. Crustacea

3.16.2.1. Introduction

The major crustacean classes are the Branchiopoda (water fleas and brine shrimp), the Maxillopoda (copepods and barnacles), the Ostracoda, and the Malacostraca (amphipods, isopods, and decapods). The decapods include the familiar crabs, crayfish, shrimp, and lobsters. Crustaceans are found in a wide variety of habitats that include marine, freshwater, and terrestrial environments and range from deep-sea thermal vents to freshwater pools in lightless caves. The adult head of crustaceans bears first and second antennae, mandibles, and first and second maxillae. Various types of appendages can be found on the thorax and abdomen. Although there are numerous orders of crustaceans, the greater part of the endocrinological work has been conducted on the Decapoda.

3.16.2.2. Molting and Metabolism

Arthropods must periodically shed their external, confining exoskeletons and take up air or water to expand their new and larger exoskeletons in order to grow in size. The problem of how to increase in body size is even more formidable for crustaceans due to their mineralized, relatively rigid exoskeletons. The molt cycle is defined as the interval between two successive molts. Drach (1939) divided the molt cycle into a series of stages associated with specific cuticular events from just after ecdysis (postmolt), through a lengthy intermolt period, to the period leading up to a subsequent ecdysis (premolt). These stages have been assigned a number of

substages, depending upon the author and the species of crustacean (e.g., Aiken, 1973, for the lobster *Homarus americanus*).

3.16.2.2.1. Ecdysteroids Horn and his colleagues (Hampshire and Horn, 1966; Horn *et al*., 1966) isolated and determined the structure of 20-hydroxyecdysone (20E) from the rock lobster *Jasus lalandei*. Although the hormone was originally called "crustecdysone" or "ecdysterone," Horn's group demonstrated the identity of 20E as the principal active form of the molting hormone from both insect and crustacean sources. In most species examined, ecdysone (E) is the prohormone secreted by the Y-organ and it is hydroxylated by target tissues to 20E (Chang and O'Connor, 1978). There are exceptions to this, however, as described below. Although 20E is the predominant molting hormone in all decapod species examined to date, other ecdysteroids (steroids structurally related to E that have molting hormone activity) have been characterized in hemolymph and tissues of various crustacean species. These include E; ponasterone A (25-deoxy-20-hydroxyecdysone); inokosterone (25-deoxy-20,26-dihydroxyecdysone); makisterone A (24-methyl-20-hydroxyecdysone); 20,26-dihydroxyecdysone; and 2-deoxyecdysone (reviews: Spindler *et al*., 1980; Skinner, 1985a; Watson *et al*., 1989; Chang, 1993). Comparisons in the absolute concentrations of various ecdysteroids between species are difficult to make due to different detection methods and the lack of standardization in the molt stage of the donor animals.

Classical morphological observations and endocrinological experiments (Gabe, 1953; Echalier, 1959) indicated that the molting gland in the crab *Carcinus maenas* was the thoracic Y-organ. Organ culture of the Y-organs from the crabs *Cancer antennarius* and *Pachygrapsus crassipes* (Chang and O'Connor, 1977) and from the crayfish *Orconectes limosus* (Keller and Schmid, 1979) resulted in the characterization of E as the primary secretory product of the Y-organ.

Other ecdysteroids are secreted by the Y-organs in other crab species: 3-dehydroecdysone from *Cancer antennarius* (Spaziani *et al*., 1989) and 25-deoxyecdysone from *Carcinus maenas* (Lachaise *et al*., 1989; see review by Watson *et al*., 1989). It is not clear why different types of ecdysteroids are secreted by the Y-organs of various species. In almost all cases examined, exogenous ecdysteroids promote progression through the molt cycle (Skinner, 1985b). Associated biological activities attributed to exogenous ecdysteroids include apolysis (separation from the exoskeleton from the underlying epidermis) (Webster, 1983), growth of regenerating limb buds (Rao *et al*., 1972; Hoarau, 1982), formation of gastroliths (McWhinnie *et al*., 1972), increased incorporation of labeled precursors into macromolecules (McWhinnie *et al*., 1972; Dall and Barclay, 1979), increased protein kinase activity (Christ and Sedlmeier, 1987), premolt behavior (Borowsky, 1980), and alterations in hemolymph osmolarity (Charmantier and Trilles, 1976).

Like vertebrate steroid hormones, ecdysteroids recognize target tissues by binding with nuclear receptors. The ecdysteroid receptor has been isolated and characterized from the fiddler crab *Uca pugilator* (Durica and Hopkins, 1996; Chung *et al*., 1998). It has been sequenced and has homologies with insect ecdysteroid receptors (see **Chapter 3.5**). Transcripts for the crab gene were isolated from limb buds and developing ovaries (Durica *et al*., 2002).

3.16.2.2.2. Molt-inhibiting hormone Hemolymph ecdysteroid concentration fluctuates dramatically during the molt cycle (e.g., from $<10\,\text{ng ml}^{-1}$ in postmolt to $>350\,\text{ng ml}^{-1}$ in premolt lobster) (Chang and Bruce, 1980) and these changes mediate the various biochemical and physiological processes that occur during the cycle. The rate of synthesis and/or secretion of E by the Y-organ varies during the molt cycle and partially explains these hemolymph fluctuations in ecdysteroid titer. Just prior to the substage of premolt in which the highest concentration of ecdysteroids was observed in the hemolymph, explanted Y-organs were found to secrete the greatest amount of E (Chang and O'Connor, 1978). Low hemolymph concentrations were correlated with low secretory rates.

Removal of both stalked eyes of *U. pugilator* resulted in a shortening of the molt interval (Zeleny, 1905). This observation lead to the postulation of an endocrine factor present in the eyestalks that normally inhibits molting – a molt-inhibiting hormone (MIH). Detailed microscopical examinations resulted in the description of a neurohemal organ in the eyestalk of several decapod crustaceans (Bliss and Welsh, 1952; Passano, 1953). This neurohemal organ is called the sinus gland and serves as a storage site for neurosecretory products. It consists of the enlarged endings of a group of neurosecretory neurons collectively called the X-organ (Hanström, 1939).

The shortened molt interval observed in eyestalk-ablated decapods is likely due to a rapid elevation in the concentration of circulating ecdysteroids, which is a result of X-organ/sinus gland removal (Chang *et al*., 1976; Chang, 1993). Conversely, the

demonstration of decreased ecdysteroid titers in eyestalk-ablated crabs that have been injected with eyestalk extracts (Hopkins, 1982; Keller and O'Connor, 1982) lends additional support to the paradigm of the MIH–Y-organ molt-controlling axis. Further evidence of this hypothesis was provided by Gersch *et al*. (1980), who demonstrated that if *O. limosus* were initially injected with sinus gland extracts, the subsequent culture of the crayfish Y-organs resulted in a decreased production of E compared to vehicle-injected animals. *In vitro* secretion of E by crab Y-organs could be inhibited when cultured with either conditioned medium that had previously been incubated with explanted sinus glands or by the addition of eyestalk extracts (Soumoff and O'Connor, 1982; Mattson and Spaziani, 1985; Schoettker and Gist, 1990).

Callinectes sapidus MIH has been cloned and the cDNA was used as a probe to show that the amount of MIH mRNA in the eyestalk neural ganglia was negatively correlated with the hemolymph concentration of ecdysteroids; for example, there were low levels of MIH mRNA in the eyestalk during premolt (Lee *et al*., 1998). Similarly, Nakatsuji *et al*. (2000) observed an increased content of MIH in the premolt X-organ/sinus gland in *Procambarus clarkii*.

MIH from *C. maenas* was among the initial MIHs to be characterized (Webster, 1991) (**Figure 1**). It is a member of a novel neuropeptide family, representatives of which have so far been found only in arthropods (Edomi *et al*., 2002). This neuropeptide family regulates such diverse functions as molting, reproduction, and metabolism (Chang, 1993; De Kleijn and Van Herp, 1995; Webster, 1998; Watson *et al*., 2001; Böcking *et al*., 2002). MIH binds to hormone receptors on the membranes of Y-organ cells (Webster, 1993) and likely mediates its action via cyclic nucleotide second messengers (Saidi *et al*., 1994) or through alterations in calcium ion fluxes and activity of protein kinase C that phosphorylates enzymes involved in steroidogenesis (Spaziani *et al*., 2001). (See **Chapter 3.2** for the role of second messengers in the modulation of E synthesis in the insect prothoracic gland.)

3.16.2.2.3. Crustacean hyperglycemic hormone and related neuropeptides Crustacean hyperglycemic hormone (CHH), initially characterized from the crab *C. maenas* (Kegel *et al*., 1989; Weidemann *et al*., 1989), contains a high degree of homology with MIH (**Figure 1**). One important role of CHH is the maintenance of glucose homeostasis. Removal of the sinus glands from *O. limosus*, leaving the remainder of the eyestalk neural tissue and vision intact, resulted in a permanent decline in hemolymph glucose. The circadian rhythmicity of fluctuations in glucose concentration was attenuated (Hamann, 1974). Hyperglycemia is commonly observed under a variety of stressful conditions, and there is considerable indirect evidence to suggest that stress-induced hyperglycemia is caused by the release of CHH (Kleinholz and Keller, 1979; Keller and Sedlmeier, 1988; Webster, 1996). For example, under hypoxic conditions, glucose may be released by CHH from carbohydrate stores to serve as a substrate for glycolysis and lactate formation, as is typical for anaerobiosis of decapod crustaceans. After 4 h of emersion, which causes anoxia, the CHH concentration in lobsters rose from $<10\ \mathrm{fmol\ ml^{-1}}$ to approximately $200\ \mathrm{fmol\ ml^{-1}}$ (Chang *et al*., 1998). In addition to hyperglycemia, other demonstrated actions of CHH in crustaceans include lipid mobilization (Santos *et al*., 1997), secretory activity of the hepatopancreas (Sedlmeier 1988), and second-messenger responses in various tissues (Sedlmeier and Keller 1981; Goy *et al*., 1987).

Figure 1 Amino acid sequence of *Carcinus maenas* crustacean hyperglycemic hormone (Cam-CHH) and molt-inhibiting hormone (Cam-MIH) (Kegel *et al*., 1989; Webster, 1991). In *C. maenas* (Weidemann *et al*., 1989) and *Orconectes limosus* (De Kleijn *et al*., 1994), the CHH preprohormone has a 26-amino acid signal peptide. At the C-terminus, the signal peptide is followed by a 38-amino acid CHH precursor-related peptide (CPRP) in *C. maenas*. The CPRP is 33 amino acids long in both *O. limosus* and *Homarus americanus* (Tensen *et al*., 1991; De Kleijn *et al*., 1995). The actual CHH peptide is located at the C-terminal end of the CPRP. MIH from *C. maenas* has 78 amino acid residues with six cysteines and unblocked N- and C-termini. The MIH precursor consists of a 35-amino acid residue signal peptide and the 78-amino acid mature MIH (Klein *et al*., 1993).

Chung *et al.* (1999) observed a dramatic rise in the late premolt concentration of CHH in *C. maenas* compared to intermolt values (over 100-fold). This surge in CHH triggers the massive ion and water uptake during ecdysis and mediates the body's expansion necessary for successful ecdysis. The mechanism of this uptake is unknown, but the source of this premolt surge in CHH is paraneurons in the foregut and hindgut (Webster *et al*., 2000).

Another member of this peptide family is mandibular organ-inhibiting hormone (MOIH). The mandibular organ synthesizes and secretes methyl farnesoate (MF). MF is discussed in detail below (see Section 3.16.2.2.4). MOIH prevents the synthesis and secretion of MF *in vitro*. MOIHs have been characterized from the crabs *Cancer pagurus* (Wainwright *et al*., 1996, 1998) and *Libinia emarginata* (Liu *et al*., 1997). There are indications that additional factors regulate MF synthesis by the mandibular organ. Although injected sinus gland extracts inhibited hemolymph levels of MF by 60–80% in *C. pagurus*, equivalent amounts of injected MOIH had little effect upon MF *in vivo* (Borst *et al*., 2002).

Another member of the CHH hormone family is the vitellogenesis-inhibiting hormone (VIH) from the lobster *H. americanus* (Soyez *et al*., 1991). This peptide was isolated with the use of a heterologous assay involving the inhibition of yolk synthesis in eyestalk-ablated shrimp *Palaemonetes varians*. A VIH was also characterized from an isopod (Grève *et al*., 1999). This peptide should perhaps be renamed "gonad-inhibiting hormone" because it can be found in both sexes of the lobster *Nephrops norvegicus* (Edomi *et al*., 2002).

It is clear that members of the MIH/CHH/MOIH/VIH neuropeptide family are closely related and regulate the major physiological processes of crabs and other crustaceans. This peptide family can be divided into two subgroups (review: Böcking *et al*., 2002). Peptides belonging to the CHH subgroup are encoded by exons that include a translated CHH precursor-related peptide (CPRP). This CPRP is cleaved from the CHH prohormone to produce mature CHH. Genes coding for peptides belonging to the MIH/MOIH/VIH subgroup do not code for a CPRP (**Figure 2**). These hormones may have physiological relevance beyond the process implied by the names given to these peptides.

The use of molecular techniques has permitted a number of studies on the structure and expression of the CHH family genes. In *Carcinus maenas* (Weidemann *et al*., 1989) and *O. limosus* (De Kleijn *et al*., 1994), the CHH preprohormone has a signal peptide at the N-terminus (**Figure 2**). The signal peptide is followed by a CPRP. The actual CHH peptide is located at the C-terminal end of the CPRP. Although the function of the CPRP is unknown, it can be found in the circulating hemolymph and hence may have an endocrine function that has yet to be identified (Wilcockson *et al*., 2002).

Two distinct genes for *O. limosus* CHH have been characterized by De Kleijn *et al.* (1994). The genes code for preprohormones that differ slightly in their signal peptides and their CPRPs, but are identical in their CHH coding regions. The two genes are

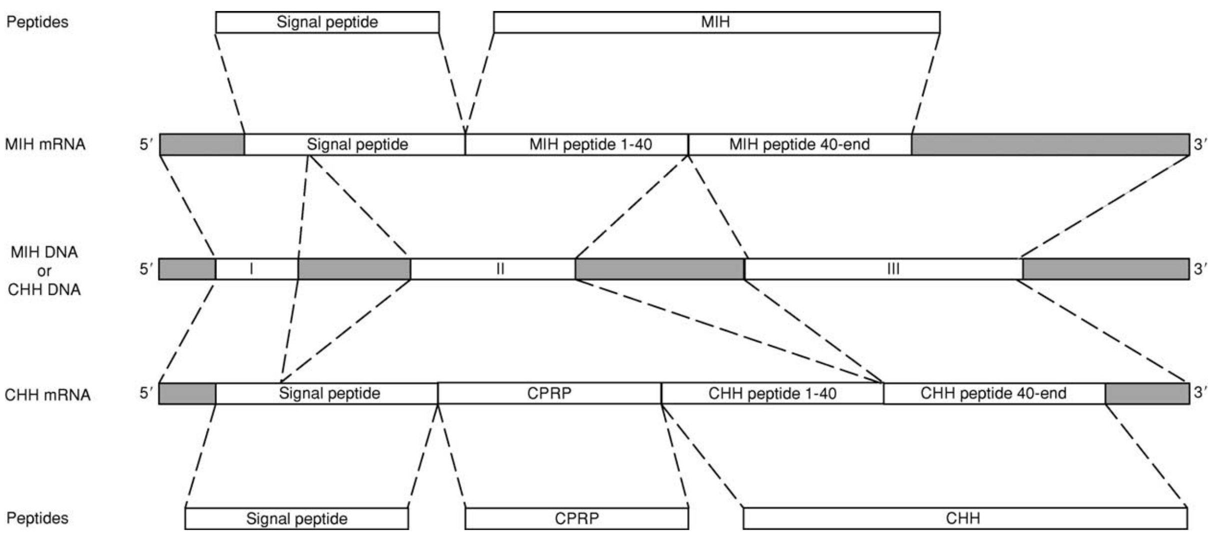

Figure 2 Schematic representation of the DNA, mRNA, and peptide structures of the CHH/MIH family of peptides. The mRNAs and peptides of MIH are shown above the central DNA. The mRNAs and peptides of CHH are shown below the central DNA. CHH, crustacean hyperglycemic hormone; CPRP, CHH precursor-related peptide; MIH, molt-inhibiting hormone. (Reproduced with permission from Böcking, D., Dircksen, H., Keller, R., 2002. The crustacean neuropeptides of the CHH/MIH/GIH family: structures and biological activities. In: Wiese, K. (Ed.), The Crustacean Nervous System. Springer, Berlin, pp. 84–97; © Springer-Verlag.)

expressed in different amounts in different individuals. Since both genes code for the identical CHH peptide, the two observed CHH isoforms must be the result of posttranslational modification. In contrast to the ratio of the mRNAs from the two CHH genes, the ratio of the two CHH peptide isoforms is similar in individual crayfish (De Kleijn *et al.*, 1994). De Kleijn *et al.* (1995) also sequenced genes coding for CHH-A and CHH-B in *H. americanus*. They observed DNA sequence variations between the two genes that resulted in amino acid substitutions in the signal peptides, the CPRPs, and the CHH peptides.

Recent research indicates that some of the isoforms seen in the CHH family are due to the occurrence of isomers of specific amino acid residues. Soyez *et al.* (1994) observed two isoforms of both CHH-A and CHH-B and determined that these isoforms were due to the presence of either the L- or D-configuration of phenylalanine at the third position (Phe^3). A similar observation was made in another crayfish by Aguilar *et al.* (1995). Injection of the different isoforms resulted in different temporal responses. [L-Phe^3]CHH-A produced maximal hyperglycemia after 2 h; [D-Phe^3]CHH-A produced its maximal effect after 3–4 h (Soyez *et al.*, 1994). The levels of hyperglycemia produced by the two isoforms, however, were the same. The release rate of each of the isomers in *O. limosus* was similar under basal conditions (Ollivaux and Soyez, 2000).

Yasuda *et al.* (1994) observed a similar phenomenon in the CHH of *Procambarus clarkii* (Prc-CHH). Prc-CHH-I has an L-Phe^3, while Prc-CHH-II has a D-Phe^3. The two isoforms had similar hyperglycemic activities but Prc-CHH-II had ten-fold greater MIH activity in an *in vitro* Y-organ assay. The authors concluded that this isomerism could explain the differential biological effects of CHH (hyperglycemia and molt inhibition).

There are multiple copies of some members of the peptide family. There are at least two copies of the MIH gene and between three and ten copies of the MOIH gene in *Cancer pagurus* (Tang *et al.*, 1999; Lu *et al.*, 2000). The function of these multiple copies and the possibility of differential regulation remain to be determined. Sufficient sequence data have now been accumulated to permit the construction of a dendrogram of the family and the identification of conserved sequence motifs (Lacombe *et al.*, 1999). The arrangement and expression of genes of the CHH family have been reviewed in greater detail by De Kleijn and Van Herp (1995), Van Herp (1998), and Böcking *et al.* (2002).

As more DNA probes for the peptide family become available, researchers will be able to address the factors that influence transcription of the genes. Changing levels of peptide transcripts can be measured throughout the molt cycle (Reddy *et al.*, 1997; Lee *et al.*, 1998). Whether these differences during the molt cycle are due to differential transcription rates (as opposed to differential degradation or processing) remain to be determined.

Progress has been made in the synthesis and expression of recombinant CHH peptides. Using *Escherichia coli*, MIH from *Marsupenaeus japonicus* (Ohira *et al.*, 1999) and from *Metapenaeus ensis* (Gu *et al.*, 2001) were expressed successfully with biological activity. Other expression systems have used the yeast *Pichia pastoris* (Sun, 1997; Ohira *et al.*, 2003) and insect cells with a baculovirus (Lee and Watson, 2002). Crayfish (*Procambarus clarkii*) MIH has been chemically synthesized (Kawakami *et al.*, 2000). The availability of large quantities of biologically active peptides will certainly be important for more detailed physiological studies.

Release of CHH from the X-organ/sinus gland is stimulated by neurotransmitters such as serotonin. When 10 μM of serotonin was applied to crayfish eyestalk neural tissue *in vitro*, CHH secretion increased by 46% over control values (Escamilla-Chimal *et al.*, 2002). Enkephalins may act in an inhibitory manner upon CHH secretion. The application of 1.0 nM of Met-enkephalin and 0.1 μM of Leu-enkephalin resulted in a significant inhibition of CHH by crayfish eyestalk ganglia *in vitro* (Ollivaux *et al.*, 2002).

There are several reports indicating the synthesis and release of CHH family peptides from neurons from noneyestalk locations (Keller *et al.*, 1985; De Kleijn *et al.*, 1995; Chang *et al.*, 1999; Gu *et al.*, 2000; Dircksen *et al.*, 2001; Lu *et al.*, 2001; Yang and Rao, 2001). These locations include the subesophageal, thoracic, and abdominal ganglia, and the second roots of the thoracic ganglia. In the lobster, these ganglia or roots each contain <50 fmol of CHH, compared to the sinus glands, which each contain 1–5 pmol of CHH (Chang *et al.*, 1999). These extra-eyestalk sources of CHH may make small contributions to systemic glucose regulation but may be even more significant in terms of localized regulation of cellular glucose metabolism. For example, under periods of stress, localized release of CHH could be important in meeting elevated metabolic requirements of neural cells. It is also possible that the extra-eyestalk material could serve a neuromodulatory role by altering the response of nerves to transmitters or other hormones. Such a function has been ascribed to other "classical" crustacean eyestalk hormones, such as red pigment-concentrating hormone (RPCH).

Extra-eyestalk CHH may also mediate functions that are distinct from glucose metabolism. As introduced above, paraneurons have been described in distinct areas of the *Carcinus maenas* foregut and hindgut (Chung *et al.*, 1999; Webster *et al.*, 2000). These cells express CHH only during ecdysis and are likely the source of the CHH surge during ecdysis that mediates water uptake. In the crab *Pachygrapsus marmoratus*, CHH from the X-organ/sinus gland was observed to increase sodium flux in the gill (Spanings-Pierrot *et al.*, 2000). In the crayfish *Astacus leptodactylus*, the D-Phe^3 form of X-organ/sinus gland CHH had a higher level of biological activity compared to the L-Phe^3 form when assayed for an increase in hemolymph osmolality (Serrano *et al.*, 2003). An insect representative of the CHH peptide family has been identified in the locust *Schistocerca gregaria* as an ion-transport peptide that mediates ion and water balance (Audsley *et al.*, 1992a, 1992b).

Another extra-eyestalk source of a CHH-like peptide is the pericardial organs. Surprisingly, the C-terminal CHH from these thoracic organs has a different amino acid sequence from that of the X-organ/sinus gland CHH. The function of this peptide is not known since it does not have CHH or MIH activities (Dircksen *et al.*, 2001).

Much has been learned about the structure–function relationships of CHH peptides. The solution structures of CHH and MIH were elucidated by Katayama *et al.* (2003) and the α-helices have been mapped. The N-terminal pyroglutamate of *C. maenas* CHH does not seem to have a significant function compared to an unblocked glutamate, at least in regards to the known activities of CHH (Chung and Webster, 1996). In contrast, the C-terminal valine-amide of *M. japonicus* CHH had 10 times the hyperglycemic activity compared to the CHH with an unmodified C-terminal valine (Katayama *et al.*, 2002).

3.16.2.2.4. Methyl farnesoate The mandibular organ produces a sesquiterpenoid, MF (**Figure 3**), related to the insect juvenile hormone (JH) (see **Chapter 3.7**). Methyl farnesoate was initially isolated from *L. emarginata* (Laufer *et al.*, 1987) and from several other decapods (Borst *et al.*, 1987). Several different effects on crustacean development and reproduction have been attributed to MF (review: Homola and Chang, 1997), including control of the duration of the molt interval. When MF was added to the water in which lobster larvae were cultured (Borst *et al.*, 1987), there was a small but significant increase in the time to metamorphosis compared to control larvae (1.2 day increase with 1 μM MF). These observations are consistent with the hypothesis that MF is acting as a crustacean JH in that it promotes the retention of juvenile characteristics. There were, however, no significant changes in the morphology of the larval lobsters.

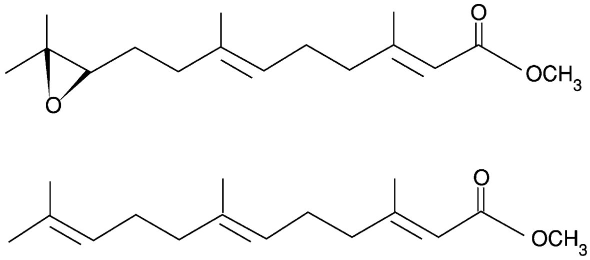

Figure 3 Structure of juvenile hormone III (top) and methyl farnesoate (MF) (bottom).

Yudin *et al.* (1980) observed that implantation of blue crab mandibular organs into white shrimp *Litopenaeus setiferus* resulted in shortened intermolt periods accompanied by more frequent molting and the molt stimulation was not due to ecdysteroid secretion by the mandibular organ. Tamone and Chang (1993) observed that application of MF increases the synthesis and/or secretion of ecdysteroids by the Y-organ. Y-organs from *Cancer magister* were incubated with various concentrations of MF. In the presence of MF, the organs secreted about 50% more ecdysteroids into the medium after 24 h when compared to controls. The magnitude of this stimulation increased with higher concentrations of MF and increasing incubation times. However, this ecdyisotropic effect has not been seen in other species (Spaziani *et al.*, 2001). In addition to molt interval effects, MF inhibits allometric growth of claws in crabs (*Libinia emarginata*). The mechanism of this inhibitory action is unknown (Laufer *et al.*, 2002).

Hemolymph MF-binding proteins have been characterized in the few crustacean species examined. Prestwich *et al.* (1990) characterized a 40 kDa protein in the hemolymph of *H. americanus* that bound a photoaffinity analog of MF (farnesyl diazomethyl ketone) (Ujváry and Prestwich, 1990). Binding of ^{3}H-farnesyl diazomethyl ketone was prevented in the presence of excess unlabeled MF. MF-binding proteins were also observed in the hemolymph of the shrimp *Sicyonia ingentis* (Chang *et al.*, 1992), the crayfish *Procambarus clarkii* (King *et al.*, 1995), and the crabs *L. emarginata* (Li and Borst, 1991) and *C. magister* (Tamone *et al.*, 1997). These binding proteins may facilitate the solubility and transport of MF in the hemolymph since the hormone is very hydrophobic (see **Chapter 3.7** for

studies on the insect juvenile hormone binding proteins).

Methyl farnesoate may also be involved in mediating various stress responses. Hemolymph levels of the hormone rise following challenges with heat stress, hypoxia, and hypo- and hypersalinity (Lovett *et al.*, 1997, 2001), but it is not known how MF helps the crustacean cope with these environmental stresses. Methyl farnesoate also acts as a sex determinant. In *Daphnia magna*, application of physiological amounts of exogenous MF (400 nM) to egg-maturing females resulted in all-male broods. There was a correlation with lower MF concentrations and increasing proportions of males in the broods (Olmstead and LeBlanc, 2002).

3.16.2.3. Pigmentary Hormones

There are two types of pigmentary effectors in the Crustacea: the chromatophores and the retinal pigment cells. The chromatophores are located primarily in the integument and their activities result in the body pigmentation of the individual animal. The retinal pigments are located in the compound eyes and they regulate the amount of light impinging on the rhabdom, the light-sensitive portion of each ommatidium (the functional unit) of the compound eye.

3.16.2.3.1. Color adaptation The chromatophores are pigment-containing cells that occur in the integument and internal organs. Their function is to adjust the body coloration to its surroundings, depending upon the situation (e.g., protection, mating behavior, antagonistic displays). When the pigment granules are spread out along the extensions of the chromatophore, they are described as being in a dispersed state. In this state, the granules are most visible and give the chromatophore its characteristic color. When the granules are withdrawn from the extensions of the chromatophore, they are in a concentrated state and are not as visible.

In addition to hastening the molt, eyestalk ablation of crustaceans results in a dramatic darkening or lightening of the body color (Koller, 1927). The fact that injection of eyestalk extracts could reverse the color changes induced by eyestalk ablation (Perkins, 1928) indicated that the regulation of body color is under hormonal control. Early observations indicated that the sinus gland was a storage site for neurosecretory material that regulated color change (chromatophorotropins). However, the chromatophorotropins are located not only in the X-organ/sinus gland complex, but in other neural tissue as well (see Rao (1985, 2001) and Fingerman (1988) for a more thorough discussion).

α-PDH N[1] S G M I N S I[11] L G I P R V M T E A_{NH2}

RPCH pE[1] L N F S P G W_{NH2}

Figure 4 Amino acid sequences of pigment-dispersing hormone (PDH) and red pigment-concentrating hormone (RPCH) from *Pandullas borealis* (Fernlund and Josefsson, 1968; Fernlund, 1976).

There are two general classes of pigmentary effector hormones: the RPCH and the pigment-dispersing hormone (PDH) (see Section 3.16.2.3.2) families. The first crustacean chromatophorotropin to be sequenced was RPCH from the eyestalks of the shrimp *Pandalus borealis* (Fernlund and Josefsson, 1968, 1972; Fernlund, 1974a, 1974b). Its amino acid sequence is shown in **Figure 4**. Some publications refer to this molecule as erythrophore (red chromatophore) concentrating hormone. In addition to the erythrophores, however, other types of chromatophores are concentrated with RPCH (Josefsson, 1975, 1983a, 1983b).

Red pigment-concentrating hormone is a member of a family of structurally related peptides which includes the adipokinetic hormone (AKH) of insects (see **Chapter 3.10**). Interestingly, although there is biological cross-reactivity between the insects and crustaceans (i.e., crustacean RPCH has AKH activity in insects and vice versa), the functions of the hormones are quite distinct in the two taxonomic groups (i.e., AKH does not appear to alter lipid mobilization in crustaceans).

3.16.2.3.2. Retinal pigments There are three retinal pigments in the compound eyes of shrimp and other decapod crustaceans. This distal retinal pigment is found within cells that extend from the distal ends of the retinular cells to the cornea. The proximal retinal pigment is contained within the retinular cells. The reflecting retinal pigment is contained within cells that are variously located between the neighboring ommatidia, depending upon the species.

These three pigments alter their cellular locations in concert such that their combined activities result in either more or less light impinging upon the rhabdom, depending upon the ambient light intensity. In dim light or darkness, the light-sensitive rhabdom is exposed by the movement of the distal and proximal pigments. In addition, the reflecting pigment is located distally to the basement membrane in a position that permits light to be reflected onto the rhabdom. In bright light, the distal and proximal pigments move to screen the rhabdom from excess light. In addition, the reflecting pigment is positioned adjacent to the basement membrane.

In this position, it does not reflect light onto the rhabdom.

Pigment-dispersing hormone was first isolated and its structure determined from the eyestalks of *P. borealis* (Fernlund, 1976) (**Figure 4**). It was initially referred to as the distal retinal pigment light-adapting hormone because of its action on the distal retinal pigment (Fernlund, 1971). Later studies (Kleinholz, 1975) demonstrated that this molecule was able to disperse the pigment granules in several types of chromatophores and it is now called PDH. Several additional members of the PDH family have been isolated and information has been obtained on the molecular organization of PDH genes. The PDH precursor contains a signal peptide, a precursor-related peptide, a cleavage site, the PDH peptide, a glycine, and one or two basic amino acids (Rao, 2001).

3.16.2.4. Reproduction

3.16.2.4.1. Female Ecdysteroids likely play a role in crustacean reproduction (review: Subramoniam, 2000). Various ecdysteroids have been identified in follicle cells and oocytes of brine shrimp (Spindler *et al.*, 1984), amphipods (Blanchet *et al.*, 1979), crabs (Lachaise *et al.*, 1981; Chaix and de Reggi, 1982; Lachaise and Hoffmann, 1982; Okazaki and Chang, 1991), crayfish (Spindler *et al.*, 1984), and shrimp (Spindler *et al.*, 1987; Wilder *et al.*, 1990). The function of these ovarian ecdysteroids in crustaceans remains uncertain although some correlations between vitellogenesis and hemolymph ecdysteroid titers have been reported (Lachaise *et al.*, 1981; Chaix and de Reggi, 1982). For unknown reasons, the effects of ecdysteroid injections or *in vitro* incubations have been either inhibitory or stimulatory (Adiyodi, 1985; Chang, 1989).

Varying levels of ecdysteroids have also been found in crustacean embryos. The published studies have shown either a general rise (Spindler *et al.*, 1987; Okazaki and Chang, 1991; Chang *et al.*, 1992) or decline (Wilder *et al.*, 1990; Okazaki and Chang, 1991) in ecdysteroids from ovulation to hatch, depending upon the species. In some studies, a greater sampling frequency has demonstrated peaks of ecdysteroids (Chaix and de Reggi, 1982; Lachaise and Hoffmann, 1982; Funke and Spindler, 1987; Spindler *et al.*, 1987; Goudeau *et al.*, 1990).

In addition to its effects upon the molt interval previously described, there are observations that MF is a gonadotropin (compare with the actions of JH in insects (see **Chapter 3.9**). Early, indirect studies involved eyestalk ablation and subsequent ovarian maturation. For example, mandibular organs (the source of MF) from immature female crabs secreted approximately 500 pg of MF per hour, the secretion rate being six times higher in female crabs with maturing oocytes (Laufer *et al.*, 1987; reviewed in Laufer and Biggers, 2001). Direct experiments involved the injection of exogenous MF into eyestalk-ablated crabs, *L. emarginata* (Vogel and Borst, 1989). Following injection, these crabs had an increased level of hemolymph yolk proteins. Enhanced egg production was observed in the shrimp *Litopenaeus vannamei* that had previously been administered exogenous MF (Laufer, 1992). Similar experiments resulted in increased ovarian maturation in the crayfish *Procambarus clarkii* (Laufer *et al.*, 1998; Rodriguez *et al.*, 2002) and the crab *Oziotelphusa senex* (Reddy and Ramamurthi, 1998).

3.16.2.4.2. Male Charniaux-Cotton (1954) proposed various actions of the androgenic gland in a male amphipod (*Orchestia gammarella*). This gland caused masculinization when it was implanted into a female and feminization or dedifferentiation when it was removed from a male (review: Charniaux-Cotton, 1985). Subsequent research used bioassays based upon the masculinization of young female isopods. Protein blotting experiments with polyclonal antisera raised against androgenic gland hormone (AGH) indicated the presence of a larger, biologically inactive protein. It was deduced that AGH was translated as a prohormone (Martin *et al.*, 1990; Hasegawa *et al.*, 1991). From the isopod *Armadillidium vulgare*, Martin *et al.* (1999) and Okuno *et al.* (1999) completed the DNA sequencing of the AGH gene. Pro-AGH consists of a B chain, a C peptide, and an A chain. This suggests that the structure of pro-AGH is analogous to that of vertebrate proinsulin. Recombinant isopod AGH has been produced (Okuno *et al.*, 2002). Secretions from the X-organ/sinus gland complex may regulate the androgenic gland since eyestalk ablation resulted in hypertrophied androgenic glands in crayfish (Khalaila *et al.*, 2002).

Other biologically active factors have been isolated from a crab (*Carcinus maenas*) androgenic gland e.g., the terpenes farnesylacetone and hexahydroxyfarnesylacetone were isolated. They inhibited the incorporation of radiolabeled leucine by ovaries *in vitro* (Ferezou *et al.*, 1977). Farnesylacetone also inhibited radiolabeled uridine incorporation, suggesting that it may inhibit transcription (Berreur-Bonnenfant and Lawrence, 1984). The

role of these terpene androgenic gland factors remains conjectural in decapods. They likely are not the AGH, however (review: Sagi and Khalaila, 2001).

3.16.2.5. Limb Autotomy and Regeneration

Decapods have an amazing ability to regenerate limbs, and crabs have been the primary experimental animals for research in this area. There is a direct correlation between the increase in circulating ecdysteroids during premolt and the growth of limb buds (Hopkins, 1989). Recent evidence indicates that retinoids may be involved in the regenerative process (Hopkins, 2001).

Skinner (1985b) observed that the temporal occurrence of autotomy (self-induced leg loss) during the molt cycle influenced the length of the molt interval. Using the crab *Gecarcinus lateralis*, she observed that loss (and hence initiation of regeneration) of five or more limbs during the intermolt stage resulted in a shortened molt interval. This has lead to the postulation of an endocrine factor that is synthesized/released upon multiple limb autotomy in anecdysis (intermolt) and that shortens the molt interval. This factor is called limb autotomy factor–anecdysial (LAF_{an}) (Holland and Skinner, 1976; Skinner, 1985b).

The other postulated factor, which is thought to be responsible for the proecdysial (premolt) lengthening of the molt interval, is called limb autotomy factor–proecdysial (LAF_{pro}). In *G. lateralis*, autotomy of a partially regenerated limb bud before a critical period during premolt delays molting. A secondary limb bud forms at the autotomized primary limb bud and molting is delayed such that this secondary limb bud is able to catch up in growth to any remaining primary limb buds (if present) and enables the crab to molt with a complete set of walking legs (Mykles, 2001). Yu *et al.* (2002) hypothesize that LAF_{pro} inhibits molting by suppressing Y-organ secretion of ecdysone. Autotomy of primary limb buds reduced the circulating ecdysteroid concentration by 73% after 1 week. Injection of secondary limb buds extracts, but not primary limb bud extracts, resulted in inhibition of primary limb bud growth. Not much is known about the chemical nature of these limb-related factors.

The vertebrate pineal hormone, melatonin, has been characterized in several invertebrate groups, including crustaceans. When it was added to the culture medium of regenerating crabs (*U. pugilator*), the rate of regeneration of their limb buds increased (Tilden *et al.*, 1997). Any relationship between melatonin and the limb autotomy factors is unknown.

3.16.2.6. Conclusions

This is an exciting time for research on crustacean endocrinology. There is increased interest in the topic due to aquaculture applications and the focus on crustaceans as keystone species in aquatic environments. Some key areas of future research include the following:

1. Y-organs secrete several different ecdysteroids. Does an individual species secrete only a single ecdysteroid during the molt cycle or is there a variety of secreted products? Why is there variation in the secreted ecdysteroid amongst species? In eyestalk-ablated crustaceans, which lack MIH, why do circulating levels of ecdysteroids continue to cycle with a peak in late premolt and basal levels in postmolt? There must be regulation of the Y-organ other than simple MIH inhibition.
2. Except for the ecdysteroid receptor, research on crustacean hormone receptors has been minimal. The characterization of MF and peptide hormone receptors will yield insight into the molecular action of these molecules.
3. New functions are being attributed to members of the CHH peptide family. Structure–function studies of the peptides will yield information about key amino acid positions and their resulting biological activities. An example of the significance of using this as a model system is seen with studies on the Phe^3 posttranslational isomerism.
4. Further research on the biological activities and mode of action of MF will be of comparative interest in relation to JH studies in insects. Both the developmental and reproductive aspects of MF need to be addressed.
5. There have been dozens of publications on various narrowly focused aspects of the hormonal control of reproduction. These studies examined neurotransmitters, VIH peptides, ecdysteroids, MF, or vertebrate-like steroids (such as estrogen or progesterone). The interactions between these factors will certainly be difficult to dissect experimentally. However, these experiments will need to be conducted in order to clarify what is currently a very confusing situation.
6. There is growing interest in the field of aquatic endocrine disrupters (deFur *et al.*, 1999). Since much is known about the endocrinology of crustaceans, and since crustaceans are often keystone species in aquatic food webs, there will likely be much more research devoted to the determination of the effects of exogenous chemicals upon

these various hormonal processes. Crustaceans will likely be useful indicator species for environmental contamination.

3.16.3. Chelicerata

3.16.3.1. Introduction

The major chelicerate classes are the Merostomata (horseshoe crabs), which are the closest living relatives of the trilobites (Shuster, 1982), the Pycnogonida (sea spiders), and the Arachnida. The latter is divided into seven minor, and three major, orders, the latter being: Scorpiones (scorpions), Araneae (spiders), and Acari (mites and ticks).

The chelicerate body is divided into an anterior prosoma, which bears the mouthparts and walking legs, and a posterior opisthosoma, which bears appendages in some groups (e.g., the Merostomata) or which lacks them entirely (e.g., the Arachnida). The chelicerates lack antennae, and their mouthparts include a pair of chelicerae, whence the name.

Most of the chelicerates have been neglected by endocrinologists. For example, the Merostomata require about 12 years (and up to 20 molts) to reach sexual maturity (Yamasaki *et al.*, 1988), and it has proven difficult to rear them from egg to adult in the laboratory (Sekiguchi *et al.*, 1988). The Pycnogonida are elusive creatures, found exclusively on the seabed, and very little in general is known about them (King, 1973). Although scorpions are relatively large, are of medical importance, and survive well in captivity, they have extraordinarily low metabolic rates and long generation times (Polis, 1990), characteristics not amenable to the design of endocrinological experiments. As for pseudoscorpions, there have been only about 200 entries in total on them between 1980 and 2004 in *Biological Abstracts*, and none on any aspect of their endocrinology.

Thus, our main focus will be on the endocrinology of spiders, mites, and ticks. Note also that sometimes the most recent endocrinological studies on these groups were published more than 10 years ago, which accounts for why this section of this chapter will seem more dated than most of the material presented in this series.

3.16.3.2. The Neuroendocrine Systems of the Chelicerata

3.16.3.2.1. Merostomata Jegla (1982) hypothesized that the median and/or lateral rudimentary eyes of the so-called "trilobite larva" of horseshoe crabs might be the merostomatan analog of the crustacean X-organ/sinus gland. However, the molt cycle was not significantly affected when he ablated them (laser irradiation) in a systematic manner and at various times between hatching and molting. He concluded:

> We do not know whether horseshoe crabs have a control system for molting that includes a neurohormone and a molting gland, let alone whether there may be an inhibitory control as in crustaceans or a stimulatory one as in insects.

The question remains unexplored since then.

3.16.3.2.2. Pycnogonida Some neurosecretory cells (NSCs) have been recognized in the sea spider brain, and a so-called "Sokolow's organ" has been found beneath the eyes and lateral to the optic lobes. This may be the pycnogonid counterpart of the X-organ/sinus gland of Crustacea, although any evidence for homology or function is absent (King, 1973). A series of paired, segmentally arranged "ventral organs" (possibly neurosecretory structures) develops in association with the neural ganglia. No other putative endocrine tissue has been identified (King, 1973; Arnaud and Bamber, 1987).

3.16.3.2.3. Arachnida: the "minor" orders Legendre (1985) has reviewed what is known about the neuroendocrine systems of seven minor orders of Arachnida: Ricinulei, Uropygi (whipscorpions), Palpigrada (microwhipscorpions), Solifugae (windscorpions), Amblypygi (whipspiders), Pseudoscorpiones, and Opiliones (harvestmen). In all cases, groups of NSCs have been observed (usually by paraldehyde fuchsin staining), at least in the cerebral ganglia. In some cases putative neurohemal organs have also been identified (Solifugae, Amblypygi, Pseudoscorpiones, and Opiliones). Details are provided by Legendre (1985). No further studies relating to their endocrinology were found.

3.16.3.2.4. Arachnida: Scorpiones The cephalothoracic nerve mass of scorpions contains numerous neurosecretory centers distributed in a way that reflects the metameric plan, but their specific functions have not been determined (Root, 1990). A factor isolated from the cephalothoracic mass of the Indian scorpion, *Heterometrus fulvipes*, raises sugar concentration in the hemolymph and in the hepatopancreas, although whether its source is from NSCs is not known (Root, 1990). An antiserum against *Homarus americanus* CHH (Hoa-CHHA) stains specific NSCs and associated structures in *Euscorpius carpathicus*, but the physiological

significance of this material is not known (Stockmann *et al.*, 1997).

Juberthie and Bonaric (1990) review the literature dealing with putative molting glands in scorpions, but for all such suggestions, direct evidence is lacking.

3.16.3.2.5. Arachnida: Araneae The following account is compiled from excellent descriptions of the spider neuroendocrine system by Babu (1973), Bonaric (1981), Legendre (1985), Bonaric *et al.* (1987), and Bonaric and Emerit (1995). The system comprises NSCs in the protocerebrum, two "Schneider's organs" (O.Sch.1 and O.Sch.2), the *Tropfenkomplex* (a neurohemal organ), and a molting gland. NSCs in the brain lead to O.Sch.1. Secretions originating in NSCs and O.Sch.1 enter the hemolymph via the *Tropfenkomplex*. At least one of these neurohormones probably stimulates the molting gland to secrete ecdysone (E) (see Section 3.16.3.3.4). Thus, the O.Sch.1 plus the *Tropfenkomplex* are at least analogous to the corpus cardiacum of insects. The O.Sch.1 may correspond to the intrinsic cells of the corpus cardiacum, but the role of the O.Sch.2 is not known (Bonaric, 1995).

Babu (1973) provided a detailed account of the morphology and secretory cycles of the neuroendocrine system in the orb web spider *Argiope aurantia*. Changes in stainability of the *Tropfenkomplex* generally mirrored those in the NSCs innervating it. During the intermolt of each stage, there is one peak of activity early in the instar, and a second toward the end, suggesting that the second peak is associated with molting. Moreover, NSCs in the cheliceral ganglia first become apparent only at the seventh stage, when the female attains maturity. By the 10th day of the ninth stage there occurs a prominent peak of staining in the cheliceral ganglia. As this is followed by gonad maturation and oviposition, the NSCs in the cheliceral ganglia were suggested to be involved in reproduction.

The cells of the molting gland display an ultrastructure characteristic of steroid-secreting tissue, and the secretory cycle of these cells can be correlated to the molt cycle (Bonaric and Juberthie, 1983; Juberthie and Bonaric, 1990). In nymphs of the Mediterranean spider *Pisaura mirabilis*, NSCs in the brain are active during the first half of the molt cycle, a time at which mitoses are common in the molting gland. The molting gland cells appear very active in the second half of the molt cycle, and this coincides with high levels of hemolymph ecdysteroids (Legendre, 1985). Finally, during the winter diapause, NSC activity is low in the brain and O.Sch.1, and molting does not occur (Legendre, 1985).

3.16.3.2.6. Arachnida: Acari Although the endocrinology of the Acari, especially ticks, is better known than that of any other chelicerate, our knowledge of their hormonal mechanisms remains decades behind that of the insect models covered in this volume. One reason is because not a single endocrine organ has been established with certainty in the Acari. Most mites weigh in the submilligram range, making surgery, ligation, and sampling of hemolymph virtually impossible. There has been much more success with ticks, although surgery remains difficult because the delicate gut frequently ruptures.

The ventral ganglia of insects echo the arthropod metameric pattern. In chelicerates, however, there is a considerable condensation of ganglia, and the extreme expression of this is among the Acari, where the complete central nervous system is represented by a single, anteroventral synganglion, from which all the nerve trunks radiate (Harris and Kaufman, 1984; Binnington, 1987; Evans, 1992).

3.16.3.2.6.1. Neurosecretory centers Neurosecretory centers have been well mapped in several tick species (Eisen *et al.*, 1973; Obenchain, 1974; Obenchain and Oliver, 1975; Binnington and Obenchain, 1982; Marzouk *et al.*, 1985; Binnington, 1986; Prullage *et al.*, 1992). In some cases, secretory activity has been correlated with molting, reproductive stage (virgin versus mated), oviposition and ovipositional diapause (Severino *et al.*, 1984; Hänel, 1986; Shanbaky *et al.*, 1990a). The system described by Prullage *et al.* (1992) is generally similar to those described for other ixodid ticks (Evans, 1992).

3.16.3.2.6.2. The "retrocerebral organ complex" The "retrocerebral organ complex" (ROC) has been postulated as a release site for neurosecretions in the Acari. Whereas the ROC of spiders comprises the two organs of Schneider, the *Tropfenkomplex*, and a number of nerves (Foelix, 1996), in the Acari, the ROC is a somewhat ill-defined anatomical complex of NSCs and glial matrix cells, closely associated with the esophagus as the latter emerges from the mid-posterior region of the synganglion. It is sometimes termed the "paraesophageal organ" (e.g., Roshdy *et al.*, 1973). In the mite *Dermanyssus gallinae*, the ROC is a small group of cells staining positively with paraldehyde fuchsin (Severino *et al.*, 1984). In *Dermacentor variabilis*, three major neurosecretory tracts terminate in the ROC (Obenchain and Oliver, 1975). Because of the presence of neurosecretory terminals and a close association between the sheath enveloping the ROC and the

periganglionic sinus, Obenchain and Oliver (1975) considered the ROC to be a neurohemal organ, a suggestion that has been repeated for other Acari. The staining properties of the ROC change with stages of the life cycle, but in no case is there evidence from bioassay of specific groups of cells to demonstrate a specific function.

Binnington (1987), however, could not find neurosecretory terminals in the ROC of *Boophilus microplus*. Instead, the primary sites of neurosecretory nerve terminals appear near the perineurial sheath and are generally dispersed around the circumference of the synganglion. He suggested that there is no need for a specific neurohemal organ because the aorta connects directly to the perineurial sinus which surrounds the synganglion. Thus, neurosecretory material released anywhere at the perineurial sheath will be carried directly into the main body of the hemocoel (Binnington and Obenchain, 1982). Zhu and Oliver (1991) noted that the insulin-like peptide in NSCs of *Ornithodoros parkeri* also seems to be released diffusely around the neurilemma.

3.16.3.2.6.3. The "lateral segmental organs" Binnington (1981) examined the ultrastructure of the "lateral segmental organs" (LSOs) of *B. microplus* throughout the adult stage. The LSOs present themselves as an anterior pair suspended from pedal nerve I, and a (larger) posterior pair suspended from a salivary gland (SG) nerve arising from the "lateral nerve plexus" (Harris and Kaufman, 1984). This arrangement occurs in many ticks, but in *D. variabilis* and *Argas persicus*, there are four pairs of LSOs. A few axons from the suspending nerves penetrate the LSOs (Binnington, 1981). Each organ consists of up to six similar cells. Golgi bodies are associated with an abundance of smooth endoplasmic reticulum (ER), with cisternae being generally dilated in feeding and freshly engorged females; rough ER is much less abundant (Binnington, 1981). LSOs are apparently absent in *Argas radiatus* (Marzouk *et al.*, 1985) and in *O. parkeri* (Pound and Oliver, 1982).

The LSO cells contain many lipid droplets, especially in ovipositing females (Binnington, 1981). The overall ultrastructure of these gland-like cells, and the apparent increase in activity with feeding and egg production suggest an endocrine function. In support of this hypothesis, the LSOs of engorged *Hyalomma dromedarii* are about double the diameter of those from unfed specimens (Marzouk *et al.*, 1985). Binnington (1981) suggested that the LSOs might secrete ecdysteroids or JH, and it is discussed below (see Section 3.16.3.3.6).

The LSOs and synganglion are stained by the vital dye, Janus Green B, and microsurgical procedures have been performed successfully on the synganglion of partially fed ticks (Kaufman and Harris, 1983; Harris and Kaufman, 1984). Thus, it should be possible to ablate the LSOs in newly engorged females and determine the effect on hemolymph ecdysteroid concentration, SG degeneration, vitellogenesis, egg development, or other physiological parameters.

3.16.3.2.7. Immunocytochemical identification of putative neurohormones There are three groups of NSCs in *O. parkeri*, which are detected by an antiserum to bovine insulin (Zhu and Oliver, 1991). Their function is not known, but they are detected in previtellogenic females and in third instar nymphs. So a general function in carbohydrate metabolism, or in ecdysteroidogenesis (e.g., Zhu *et al.*, 1991; Lomas *et al.*, 1997), rather than a specific role in reproduction, are reasonable possibilities. Davis *et al.* (1994) reported on similar cells in the synganglion of nymphal and adult *D. variabilis* (five of 18 groups of paraldehyde fuchsin positive NSCs are also positive to bovine insulin). The functions of these cells have not been determined although the contents of some of them change with feeding state.

Zhu *et al.* (1995) demonstrated FMRFamide immunoreactivity in many cells of the synganglion of *O. parkeri* and *D. variabilis*. FMRFamide-like material is also present near the perineurial sheath, which Binnington (1987) has suggested functions as a neurohemal organ (see Section 3.16.3.2.6.2). Thus, this material may be released into the hemolymph, but the specific function is not known (Zhu *et al.*, 1995).

3.16.3.3. Molting and Metamorphosis

3.16.3.3.1. Merostomata Horseshoe crabs hatch after undergoing four embryonic molts within 2 weeks postfertilization (Sekiguchi *et al.*, 1988). The (nonfeeding) trilobite larva molts within 20 days when held at 25 °C and a salinity of 30‰ (Jegla, 1982).

Krishnakumaran and Schneiderman (1968) were the first to test the effects of exogenous ecdysteroids on a chelicerate arthropod (mature *Limulus polyphemus*). All of the experimentals (injected with 40 μg 20E g^{-1} bodyweight (bw)) molted, though none completed ecdysis.

The so-called "*Limulus* bioassay," sometimes together with thin-layer chromatography, has been frequently used to detect ecdysteroids in horseshoe crabs. In this assay, the material of interest is

injected into a 1st stage larva, and a positive effect is indicated by apolysis, cuticulogenesis, or ecdysis. Sensitivity of the assay is approximately 200 pg 20E-equivalents (Jegla and Costlow, 1979a), and results are very similar to those achieved by radioimmunoassay (RIA) (Jegla and Costlow, 1979b).

Winget and Herman (1976) took blood from "juvenile" *Limulus* (life stages not specified, but in the weight range of 66–235 g) collected at the earliest stages of premolt. Using the *Limulus* bioassay following thin-layer chromatography, they detected bioactive material in the blood which comigrated with E, 20E, and inokosterone. Jegla and Costlow (1979b) demonstrated that extracts of *Limulus* larvae contained at least three times as much 20E equivalents during the premolt period than during intermolt.

Jegla (1982) described the histological changes of the integument occurring in the trilobite larva during the normal hatch–molt cycle of 20 days. He also reported a reduction of the premolt period by about 50%, as well as histological changes in the integument (apolysis and/or deposition of new cuticle) following injection of 20E. The amount of exogenous hormone necessary to induce molting was high (200 ng per larva) when injected 2–4 days after hatching, and mortality was high. When injected 10–12 days after hatching, however, a similar molting effect occurred at a dose of only 20 pg per larva, and mortality was low (Jegla, 1990).

Jegla (1982) extracted free ecdysteroids from the trilobite larva, resolved them by thin-layer chromatography and analyzed them by RIA and the *Limulus* bioassay. The most abundant ecdysteroid was 20E. The amount of this hormone fluctuated during the molt cycle, but achieved levels exceeding 30 ng g^{-1}.

Jegla (1982) treated eggs, embryos, and trilobite larvae of *Limulus* with farnesol, "*cecropia* oil" (crude extract from male abdomens of *Hyalophora cecropia*), synthetic *cecropia* JH, and two synthetic juvenile hormone analogs (JHAs). Larvae were injected, or treated topically, or immersed; eggs and embryos were immersed, the latter after removal of embryonic membranes. Trilobite larvae (6 days old) injected with an amount of *cecropia* oil known to be effective on *Tenebrio* pupae had no effect on development, and the synthetic JH, synthetic JHAs, and farnesol were toxic, although the doses tested were high.

In summary, ecdysteroid hormones have been detected in the Merostomata where they probably control molting. Evidence for the presence and functions of JH is lacking, and the endocrinology of reproduction has not been explored.

3.16.3.3.2. Pycnogonida Ecdysteroids have been authenticated in pycnogonid eggs, larval stages, and adults (Behrens and Bückmann, 1983; Bückmann *et al.*, 1986). Injection of 20E into 2nd stage larvae (*Pycnogonium litorale*) inhibited feeding and thus delayed molting (Bückmann and Tomaschko, 1992). So instead, the latter authors exposed larvae to 1–1000 ppm 20E in artificial sea water. Molting was accelerated when 20E was added to the sea water during days 5–9 of the larval period (Bückmann and Tomaschko, 1992).

Ecdysteroid levels in *P. litorale* are probably the highest levels recorded for any animal: up to 0.1% of body dry weight (equivalent to almost 600 μM if evenly distributed throughout the living animal) (Tomaschko, 1994). The ecdysteroids are concentrated in the cuticle and are secreted through cuticular pores when the animals are disturbed. Thus, crabs attempting to feed on pycnogonids trigger the release of ecdysteroids (mostly 20E and 20E-22-acetate) in amounts that are clearly distasteful to the predator (Tomaschko, 1994). It is not known why the high concentration in the integument does not disrupt the normal molting cycle of the pycnogonid itself.

3.16.3.3.3. Arachnida: Scorpiones Kumar (1980) injected 0.5–5.0 μg of a synthetic analog of E (3β,14α-dihydroxy-5,3-cholest-7-en-6-one) into the scorpion *Palamnaeus bengalensis* of various age classes (between 1 and 90 days; 0.2–4.5 g bw). In no case was there any sign of molting. El Bakary *et al.* (1987), using high-performance liquid chromatography (HPLC) followed by RIA, determined the whole body ecdysteroid titer in *Leiurus quinquestriatus* through the first and second larval molts. The ecdysteroid titer (mostly in the form of free 20E and more polar metabolites) fluctuated in a manner consistent with a putative role in molting. In adult *Leiurus*, it was possible to collect hemolymph. In males and females (age not specified) the ecdysteroid titer was 1.5 ng ml^{-1}. Ecdysteroid metabolites were also measured and only in the 1st stage larva did free 20E represent a majority of the ecdysteroid (67%). In the other developmental stages, 20E represented only 17–34% of the total ecdysteroid and free E was always lower than 20E. Fluctuating ecdysteroid titers were not correlated with reproductive state, and JH was not detected (El Bakary *et al.*, 1987).

3.16.3.3.4. Arachnida: Araneae and Opilionidae There is considerable evidence that molting in spiders is controlled by an ecdysteroid hormone. Krishnakumaran and Schneiderman (1968, 1970)

were the first to test the effects of exogenous ecdysteroids (~130 μg g^{-1} bw) on a spider (*Araneus cornutus*). Sixty-two percent of the experimentals (compared to 13% of controls) ceased web-spinning, entered apolysis, and secreted a new cuticle 4 weeks after injection, although all died prior to ecdysis (Krishnakumaran and Schneiderman, 1970). Hormonally treated spiders also showed significant cuticular abnormalities.

Krishnakumaran and Schneiderman (1970) performed similar experiments on the tarantula spider *Dugesiella hentzi* (16–25 μg 20E g^{-1}) 3 months after the normal season for molting. Although none molted within 60 days, three of them were injected again with 50 μg, and one injected again with 100 μg g^{-1} 20E. All either underwent apolysis, secretion of a new cuticle, and in one case, ecdysis. An attempt was also made to induce molting by injecting 20 μg 20E into a few isolated opisthosomata of *Araneus* and *Dugesiella*. Although the isolated opisthosomata survived for 7–10 days, none showed signs of molting.

There are 8–11 postembryonic stages in the spider *Pisaura mirabilis* (Bonaric, 1976). Bonaric (1976) injected nymphal stages 7–10 with 10–300 μg 20E g^{-1} bw under a variety of conditions, and determined the percentage of spiders that molted within 10 days of injection compared to controls. At 10–20 μg 20E g^{-1} bw there was a modest decrease of the intermolt period, with 63% molting within 10 days compared to 43 or 50% for the two control groups. At 100–200 μg 20E g^{-1} bw, mortality increased, but among those surviving, 81–86% molted within 10 days of injection. In no case did he observe supernumerary molts. Doses of 250–300 μg 20E g^{-1} bw were toxic.

Bonaric and de Reggi (1977) and Bonaric (1981) recorded whole body ecdysteroid levels (20E-equivalents by RIA) throughout the 22-day 8th nymphal stage of *P. mirabilis*. Ecdysteroid content averaged 150 pmol g^{-1} bw at emergence of the eighth instar, and remained in the range of 100–200 pmol g^{-1} bw for the next 16 days (Bonaric, 1981). Then the ecdysteroid content rose dramatically, peaking at 800 pmol g^{-1} bw on day 19 (2 days before ecdysis to the ninth instar) (Bonaric, 1981). All the immunoreactive material comigrated on a thin-layer chromatography with 20E (Bonaric and de Reggi, 1977). Also, injection of 20E (50 μg g^{-1} bw) at around day 10 of the molting cycle shortened the intermolt duration by several days (Bonaric, 1981).

Several tissues have been suggested as the endocrine source of E in spiders. One is the prosomal gland, an organ believed to be homologous to the prothoracic gland of insects (Bonaric *et al.*, 1984; Foelix, 1996). Another is a diffuse mass of tissue in the opisthosoma of mygalomorph spiders (Legendre, 1981). Similar tissues are found in various spiders, all appearing to be homologous organs (Bonaric, personal communication).

In the femurs of Opilionidae there are large cells resembling the oenocytes of insects (Romer and Gnatzy, 1981). As insect oenocytes synthesize ecdysteroids *in vitro* (Romer *et al.*, 1974; Romer, 1991), Romer and Gnatzy (1981) tested whether the femoral oenocytes of wild-caught harvestmen, *Opilio ravennae*, could do the same. In September and October (prior to winter dormancy), *in vitro* release of E and 20E ranged from 3.5 to 160 ng per sample. Rates of release were much lower (0.2–8.0 ng per sample) by tissues taken from animals that had entered winter diapause. From the experimental design it was not possible to prove that *de novo* synthesis of ecdysteroid had occurred. However, it is reasonable to hypothesize *de novo* synthesis because the epidermal cells of argasid ticks (Zhu *et al.*, 1991) and ixodid ticks (Lomas *et al.*, 1997) are the major source of ecdysteroid in those animals (see Section 3.16.3.3.6).

There has been an attempt to authenticate JH in spiders (Bonaric and Juberthie, 1990). Bonaric (1988), using an RIA following HPLC, found immunoreactive material (equivalent to about 20–80 pmol g^{-1} bw JH diol) during the intermolt period of eighth instar *P. mirabilis*. Although he could not confirm that any of his fractions corresponded to free JH I, JH II, or JH III, he did note the possibility that low levels of JH in the biological samples may not migrate similarly to larger quantities of authentic standard.

Bonaric (1979) injected 10 μg synthetic JH into the abdomens of crickets, which were then fed to 8th and 9th stage nymphs of wild-caught *P. mirabilis*. The crickets were offered to the spiders around the mid-period of the 22-day molt cycle. On consuming a whole cricket, the dose of JH to the spider would have been about 250 μg g^{-1} bw (Bonaric, 1979). After this treatment, neither supernumerary molts nor a delay in the appearance of secondary sexual characteristics was observed, however.

In summary, there is reasonably strong evidence for spiders that ecdysteroids play a normal role in molting, but no evidence that JH plays a morphogenetic role.

3.16.3.3.5. Arachnida: Acari: mites A large mass of the fungivorous mite *Tyrophagus putrescentiae*, at undefined stages of development, was analyzed

by HPLC and gas chromatography–mass spectrometry (GC–MS) (Sakagami *et al.*, 1992). 2-Deoxyecdysone occurred at 53 ng g^{-1} dried whole mites, and E occurred at 0.66 ng g^{-1}. Sakagami *et al.* (1992) also sprayed mites with an acetone solution of 20E (1000 ppm), or incorporated 20E in the yeast used to rear the mites. None of these treatments appeared to affect the molt cycle.

A more systematic study by Chambers *et al.* (1996) on the blood-sucking chicken mite, *Dermanyssus gallinae*, demonstrated a marked increase in ecdysteroid levels over 24 h of feeding (from 0.40 to 1.74 pg per mite in protonymphs, and from 0.98 to 4.01 pg per mite in deuteronymphs). The elevated titers were coincident with apolysis, and preceded ecdysis by less than 24 h. Content of 20E was five times higher than that of E. Ecdysteroid conjugates were present in both polar and apolar fractions, and hydrolysis with esterase and arylsulfatase enzymes increased the amount of RIA-positive material by three- to nine-fold depending on the particular fraction (Chambers *et al.*, 1996).

3.16.3.3.6. Arachnida: Acari: ticks The endocrinology of ticks has been better studied than that of any other chelicerate. In addition to their medical/veterinary importance, their relatively large size makes it possible to sample hemolymph and other tissues, and one can impose some physiological synchrony in an experimental group by feeding them simultaneously.

Ingested or injected ecdysteroids cause supermolting in argasid ticks (Connat *et al.*, 1983a; Diehl *et al.*, 1986), and the metabolic disposition of exogenous, radiolabeled ecdysteroids injected into the hemocoel has been described for several argasid and ixodid ticks (Bouvier *et al.*, 1982; Connat *et al.*, 1984, 1985, 1986, 1988; Wigglesworth *et al.*, 1985; Whitehead *et al.*, 1986; Connat and Dotson, 1988). Injected ecdysteroids are converted rapidly to polar and apolar conjugates, in which form they are stored (especially in the ovaries and eggs). In the hemolymph, the ecdysteroids tend to be mostly free 20E and E. The reader is referred to the foregoing references for further details on ecdysteroid metabolism.

As mentioned above (see Section 3.16.3.2.6.3), the LSOs have been suggested as the endocrine source for either ecdysteroids or JH (Binnington, 1981). Sonenshine *et al.* (1985) demonstrated the presence of ecdysteroids in most tissues of *Hyalomma dromedarii* and *Dermacentor variabilis*, with the highest concentrations appearing in the synganglion. It is noteworthy that when the synganglia were trimmed of the nerve plexi bearing the LSOs, ecdysteroid content was much reduced. When ^{14}C-cholesterol was injected into nymphs, some of it was converted to ecdysteroids or ecdysteroid metabolites. When tissues of the resultant adults were analyzed by autoradiography, the synganglion and lateral nerve plexi/LSOs contained more radioactivity than any other tissue (Sonenshine *et al.*, 1985).

Schreifer *et al.* (1987) demonstrated the synthesis/release of ecdysteroid by *D. variabilis* tissues, including synganglion/lateral plexus, held *in vitro*. They proposed that most of the ecdysteroid originated from the fat body, because this diffuse tissue adheres to virtually all internal organs. The foregoing results thus suggested that the LSOs and fat body are responsible for ecdysteroid synthesis in ixodid ticks, perhaps with the former secreting E and the latter converting it to 20E. Although a role for the fat body in converting E to 20E seems a reasonable conjecture, a major role for the LSOs seems less likely for the following reasons:

1. All ticks molt, but some species do not possess LSOs, e.g., *Argas radiatus* (Marzouk *et al.*, 1985) and *Ornithodoros parkeri* (Pound and Oliver, 1982).
2. Each LSO is composed of only four to six cells (Binnington, 1981), and so there is a maximum of only 25 such cells in a tick (most ticks possess two pairs of LSOs). But the adult female *Amblyomma hebraeum* produces approximately 3–4 μg of ecdysteroid during the gonotrophic cycle (Connat *et al.*, 1986). It seems difficult to imagine that such an amount of ecdysteroid could be produced by so few cells during this time.
3. Contrary to the report of Schreifer *et al.* (1987) on *Dermacentor* mentioned above, isolated synganglia of third instar *O. parkeri* (Zhu *et al.*, 1991) and adult *A. hebraeum* (Lomas *et al.*, 1997) do not synthesize ecdysteroid in culture, whereas the integument does so in both species (Zhu *et al.*, 1991; Lomas *et al.*, 1997). Thus there is autocrine control of molting in both families of ticks.
4. In the case of *A. hebraeum*, a neuropeptide is required to stimulate ecdysteroid synthesis by the integument of adult females *in vitro* (Lomas *et al.*, 1997). Nymphal integument of *O. parkeri*, however, does not require coincubation with a synganglion extract in order to synthesize ecdysteroid *in vitro* (Zhu *et al.*, 1991), even though molting in this species seems to be under neurosecretory control (Oliver and Dotson, 1993). Thus, the reason for this difference between *Ornithodoros* and *Amblyomma* is not obvious.

3.16.3.3.6.1. Family Argasidae The ingestion of ecdysteroids causes supermolting and inhibits egg development and oviposition in female *Ornithodoros moubata* (Mango *et al.*, 1976; Connat *et al.*, 1983a; Diehl *et al.*, 1986). This inhibitory effect on reproduction is usually reversed following the extra ecdysis. Pound *et al.* (1984) injected 20E into adult female *O. parkeri* and induced apolysis and cuticulogenesis.

Dotson *et al.* (1991) observed epidermal ultrastructure of *O. moubata* embryos at 8-h intervals throughout embryogenesis and larval development, and correlated the timing of embryonic and larval molts with whole body ecdysteroid titer in age-matched individuals. Free ecdysteroid content was 5 pg per embryo during the first few days of development, no peaks being associated with the first two embryonic molts. A peak of free ecdysteroid (20 pg per embryo) appeared during the deposition of the larval epicuticle and procuticle. At the larval hatch, ecdysteroid content had fallen back to 10 pg, but then rose during larval apolysis, peaking at 60 pg during deposition of the nymphal epicuticle, and falling back to 10 pg during ecdysis to the first nymph. Most of the esterified ecdysteroid arises from *de novo* synthesis rather than from maternal stores. A peak of ecdysteroid has also been associated with epicuticle formation in fifth instar nymphs (Germond *et al.*, 1982). Throughout embryogenesis most of embryonic ecdysteroid was esterified to fatty acid.

Zhu *et al.* (1994) measured whole body ecdysteroid content (by RIA) in fed third instar *O. parkeri* nymphs, and compared hormone titers to stages of the molt cycle. Most of the ecdysteroids were free E and 20E. Immediately following the meal there was a modest rise in ecdysteroid content from 1.0 to 6.2 $ng\,g^{-1}$ on day 3, at which level it remained for about a week. The ecdysteroid titer then rose again, reaching 23 $ng\,g^{-1}$ at the time of apolysis (day 13), and peaked at 33 $ng\,g^{-1}$ at the time of epicuticle deposition (day 15). The titer fell to 12 $ng\,g^{-1}$ at the time of procuticle deposition (day 17) and remained at that level at the time of ecdysis (day 19).

Fluctuating ecdysteroid concentrations in male *O. parkeri* nymphs correlate well with the molting cycle and spermatogenesis (Zhang *et al.*, 1995), and this will be discussed further below (see Section 3.16.3.4.5.4). In *O. moubata*, there is a peak of ecdysteroid in the middle of each of the five instars although the specific ecdysteroid composition varied somewhat between instars; in all instars, most ecdysteroid is esterified as apolar conjugates (Connat *et al.*, 1997).

In all studies in which immunoreactive material has been further analyzed by HPLC, the major component comigrates with E or 20E (e.g., Wigglesworth *et al.*, 1985; Dotson *et al.*, 1991; Zhu *et al.* 1994). In brief, evidence is compelling that 20E regulates molting in argasid ticks.

Connat *et al.* (1984) injected ^{3}H-ecdysone into female *O. moubata* at various times throughout the gonotrophic cycle of mated and virgin ticks. E was converted into two classes of apolar products (AP1 and AP2), only the second of which was incorporated in eggs. Free E and 20E could be recovered from AP2 following treatment with an esterase, suggesting that ecdysteroid-esters are the main storage form in the eggs. Although the function of these ecdysteroids is not known, the authors hypothesized that they are probably important hormones during embryogenesis, as is the case for some insects. Two later studies, however (Connat and Dotson, 1988; Connat *et al.*, 1988), provided evidence to suggest that AP2 is not normally metabolized to free 20E or E during embryonic development. They currently believe that the presence of AP2 in the egg may be due to nonspecific binding and may simply be one route by which the tick disposes of excess ecdysteroids.

3.16.3.3.6.2. Family Ixodidae Delbecque *et al.* (1978) were the first to authenticate the presence of ecdysteroids in ticks, by extracting ecdysteroids from nymphs at various times postfeeding. Using RIA, they found a peak of ecdysteroid at the beginning of cuticulogenesis (day 17). Using GC–MS, they confirmed the peak to consist of 95% 20E and 5% E.

In adult female *A. hebraeum*, there is a 4.3-fold increase in procuticle weight between the 4th and 7th day of feeding (Connat *et al.*, 1985). This synthesis of procuticle (first recorded by Lees (1952), precedes the rapid phase of engorgement, when the surface area of the integument must increase enormously in less than 24 h to accommodate a ten-fold increase in tick weight. Although whole body ecdysteroid content rises significantly at the time of cuticulogenesis, the hemolymph ecdysteroid titer remains low (10–20 $ng\,ml^{-1}$) (Connat *et al.*, 1985; Mao and Kaufman, 1999), so whether ecdysteroids control procuticle synthesis at this stage of the life cycle is not clear.

Stauffer and Connat (1990) carried out an elaborate study on *Amblyomma variegatum* nymphs through feeding and molting, comparing the ultrastructure of the integument with the ecdysteroid content of the ticks. A small peak of ecdysteroid was seen 3–4 days after dropping from the host

(~4 ng per tick) and a larger peak (~34 ng per tick) 10 days later. In *Amblyomma* nymphs, as just mentioned for adults, synthesis of the endocuticle occurred while ecdysteroid content was also low, again suggesting that cuticle synthesis at this time may be independent of ecdysteroids (Stauffer and Connat, 1990). The small ecdysteroid peak following the meal was coincident with mitoses in the integument and preceded apolysis. The large peak was coincident with epicuticle deposition of the pharate adult several days prior to endocuticle synthesis and ecdysis. Of particular interest in this study was the demonstration that mitosis and apolysis both began in the capitulum of the tick and followed progressively toward the prosoma and opisthosoma.

McDaniel and Oliver (1978) tested the effects of topically applied 20E and two JHAs on embryogenesis, nymphal development and spermatogenesis in *D. variabilis*, but observed mostly toxic effects. Similarly, when eggs of *Ixodes scapularis* were exposed to the JH agonist fenoxycarb, embryogenesis was not disrupted, and larvae hatched normally.

Fumigation of eggs with precocene 2 (P2), which disrupts JH synthesis in the insect corpus allatum, disrupted several parameters of development in *D. variabilis*, but there were no signs of precocious metamorphosis (Hayes and Oliver, 1981). Khalil *et al.* (1983) applied P2 to larvae and nymphs of *H. dromedarii*, either topically or by a type of fumigation by solutions in a petri dish containing ticks. Most nymphs were killed shortly after exposure, but among those that survived, the molting period was not altered, and adult structures were observed. P2 had similar effects on adults of this species (Gaber *et al.*, 1983) and of *D. variabilis* (Dees *et al.*, 1982). Khalil *et al.* (1984) applied JH I topically to *H. dromedarii* nymphs. High doses (50 μg) were toxic. The molting period was slightly prolonged (9–31%) in nymphs treated on the day of engorgement, but not when treated at other times.

In brief, treatment of several ixodid ticks with exogenous JH or precocenes does not influence molting or metamorphosis at less than toxic concentrations, and other attempts to authenticate JH in ticks have been equivocal (see Section 3.16.3.4.5.2). Nevertheless, a few studies demonstrating the presence of enzymes associated with JH metabolism have supported the concept of a JH system in ticks. For example, in *D. variabilis*, a JH-binding protein (Kulcsár *et al.*, 1989) and JH epoxide hydrolase and JH-specific esterase (JHE) (Venkatesh *et al.*, 1990) activities have been demonstrated. JHE activity in the nymphs of *D. variabilis* increased almost threefold 1 day after feeding (Roe *et al.*, 1993); JHE activity fell to low values by day 3, and remained low until molting to the adult. During this period, the ecdysteroid titer rose from barely detectable levels in newly fed nymphs to almost 1 ng per tick on days 10–12 (Dees *et al.*, 1984). Moreover, from Binnington's (1986) hypothesis that the LSOs are the most likely source for JH, Roe *et al.* (1993) tested the synganglion's ability to synthesize JH *in vitro*. They showed that synganglia of fed or unfed females incorporated ^{3}H-methionine into products that comigrated with JH III and the bis-epoxide of JH III (JHB_3) on thin-layer chromatography. From these and other data, Roe *et al.* (1993) hypothesized that elevated JHE activity early in the molting cycle of the nymph normally functions to reduce JH titer. Recalling that JH inhibits prothoracicotropic hormone (see **Chapter 3.2**) secretion in penultimate instar Lepidoptera (Nijhout, 1994), Roe *et al.* (1993) hypothesized further that the JHE-induced reduction of JH might function to trigger molting in the adult.

A more recent and exhaustive study from Roe's laboratory, however, has led to a complete reappraisal of the status of JH in *D. variabilis* and *O. parkeri*. The following results (Neese *et al.*, 2000) indicate strongly that neither of these ticks is able to synthesize a known insect JH:

1. None of seven organs (including synganglion) from several life stages of the two ticks was able to synthesize farnesol, MF, or JH (I, II, III, or JHB_3) *in vitro* from a number of radiolabeled precursors.
2. Using GC–MS, they could find no JH or JH-like compounds in extracts prepared from ticks at various stages of the life cycle, and could detect no juvenilizing activity in any of their tick extracts using a *Galleria* bioassay.
3. Connat *et al.* (1987) reported similar negative results for JH in *B. microplus* using GC–MS, even though their extracts expressed JH activity in two bioassays: inhibition of metamorphosis in pupae of *Tenebrio* and stimulation of oviposition in fed virgin *Ornithodoros*.
4. In all of the above experiments by Neese *et al.* (2000) in which there were negative results for the ticks, they showed positive results using corpora allata from three insects.

In brief, to account for the typical arthropod life stages of one or more larval and nymphal instars, it is assumed that a juvenilizing hormone is produced by ticks. But even though the extracts of at least some ticks do express JH bioactivity in insects, this hormone appears to be sufficiently different from known JHs to be recognized by current physicochemical assays.

3.16.3.4. Reproduction

3.16.3.4.1. Merostomata, Pycnogonida, Scorpiones, and the "Minor" Arachnida No work has been encountered specifically on the endocrinology of reproduction in any of these groups, perhaps for the reasons mentioned above (see Section 3.16.3.1). Only the morphology and histology of the reproductive system have been described for many members of these groups (see Kaufman (1997) for citations).

3.16.3.4.2. Arachnida: Araneae In common with those of other chelicerates, oocytes of spiders are not enveloped with a follicular epithelium, and oocyte development is asynchronous. Trabalon *et al.* (1992) describe the six stages of oocyte development of the spiders *Coelotes terrestris* and *Tegenaria domestica*: previtellogenic growth (stages 1 and 2), the vitellogenic phase (stages 3–5), and the postvitellogenic phase (stage 6). The oocytes of virgins never develop beyond stage 3 (small yolk vesicles only); mating is required to produce mature eggs (stage 6). In both spiders, the hemolymph ecdysteroid concentration (RIA) was low at stage 1 (6–7 ng ml^{-1}) and highest at around the transition between the previtellogenic and vitellogenic stages (25 ng ml^{-1} for *C. terrestris* and 18 ng ml^{-1} for *T. domestica*). Although this correlation is the only information suggesting a role for ecdysteroids in spider reproduction, at least it is in accord with what is known about the vitellogenic hormone in ticks (see Section 3.16.3.4.5.3).

Connat *et al.* (1988) conducted a study on the ability of five species of spider to metabolize ecdysteroids. Radiolabeled E or 20E was injected into the spider, or into a sample of its food (fly larvae), or into a drop of tissue culture Medium 199 for thirsty spiders (deprived of water for a week) to drink. The ecdysteroids were converted rapidly into polar and apolar metabolites. In the case of spiders which imbibed about 1 µg 20E in 20 µl Medium 199, all the hormones were metabolized within 15 min. However, spiders refused to eat larvae or drink fluid which had too high ecdysteroid content (>100 µM E) (Connat *et al.*, 1988): recall (see Section 3.16.3.3.2) that ecdysteroids are stored in the integument of pycnogonids as a feeding deterrent to crabs (Tomaschko, 1994).

3.16.3.4.3. Arachnida: Acari: mites Fecundity of the chicken mite, *Dermanyssus gallinae*, was much reduced following treatment with P2 for 4 days, but partially recovered following treatment with JH III (Oliver *et al.*, 1985). Fenoxycarb stimulated egg production in the grain mite *Acarus siro* (Thind and Edwards, 1990) but fenoxycarb, methoprene, and hydroprene were all toxic to the house-dust mite, *Dermatophagoides farinae* (Downing *et al.*, 1990).

It has been suggested that the gonotrophic cycle of mites that parasitize bee larvae may be influenced by the hormonal milieu of the host. *Varroa* mites produce eggs only when parasitizing the brood. Mites show a marked preference for drone broods and fecundity is higher in drone cells (Beetsma and Zonneveld, 1992; Boot *et al.*, 1992). Mites begin egg production a few days after the cell is capped, about five or six eggs being laid over 30 h (Beetsma and Zonneveld, 1992). The first egg (Beetsma and Zonneveld, 1992) or the second egg (Hänel, 1986) is usually a male, and the remainder are female. The male usually copulates with his sisters, and the bee and mites emerge from the cell.

Hänel (1986) correlated NSC activity in the *Varroa* synganglion with specific stages of the life cycle, and demonstrated that these changes could be induced by spraying mites with JH III. Moreover, there are correlations between mite fertility and hemolymph JH titer (RIA) in bee larvae (*Apis cerana indica* and *A. mellifera ligustica*) (Rosenkranz *et al.*, 1993):

- In worker larvae, hemolymph titer of JH (<10 pmol ml^{-1} at the time of cell capping) rose to 70–100 pmol ml^{-1} within 2 days. In the drones, hemolymph titer of JH was 50 pmol ml^{-1} at time of cell capping, and the peak value (170 pmol ml^{-1}) occurred at 3.5 days (see **Chapter 3.13**).
- There was a lower mite infestation of worker cells (4%) than drone cells (20%).
- None of the mites infesting the workers were fertile compared to 90% of the mites infesting drones.

Moreover, the sterol composition of *Varroa jacobsoni* (analyzed by GC–MS) reared on *A. mellifera* drones showed some similarities to that of the bee, with 24-methylenecholesterol being the major sterol in both species (Feldlaufer and Hartfelder, 1997). The fact that the major ecdysteroid in the bee drones is makisterone A, whereas E and 20E together account for 66% of the ecdysteroid in the mite, indicates that the latter can carry out independent synthesis of C-27 ecdysteroids from cholesterol (Feldlaufer and Hartfelder, 1997).

However, there is also the suggestion that the above correlations may be spurious. For example, Rosenkranz *et al.* (1990) examined two colonies of *A. mellifera* from Brazil and two from Germany, in which the *Varroa* infestation varied markedly.

There was little difference in JH titer among the colonies, however. In *A. mellifera carnica*, there are substantial caste differences for hemolymph JH and ecdysteroid titer in the last larval instar (Rachinsky *et al*., 1990). However, whereas the differences in JH occurred throughout the instar, those for the ecdysteroids occurred only during the spinning and prepupal stages. In brief, more direct evidence for the effect of the host's hormonal status on the endocrinology of *Varroa* reproduction is required.

3.16.3.4.4. Arachnida: Acari: ticks: family Argasidae In *O. moubata*, fertilization (which may occur before or after the meal) and blood-feeding (about 20–60 min) are both required to develop a normal clutch of eggs (Aeschlimann and Grandjean, 1973). Each female lays about 80–150 eggs following a preoviposition period of 10–15 days.

When virgin *O. moubata* engorge, vitellogenesis begins, but yolk resorption follows within 1 month, and the ovaries resemble the virgin condition by the third month; this regression is called "abortive vitellogenesis" (Germond and Aeschlimann, 1977). Such virgins will lay at least a small clutch of eggs, even if "delayed copulation" occurs up to 6 months following the original meal (Aeschlimann and Grandjean, 1973; Connat *et al*., 1986).

3.16.3.4.4.1. Neuroendocrine control of egg development Shanbaky and Khalil (1975) ligated ticks (*Argas* (*Persicargas*) *arboreus*) after feeding, such that the synganglion was isolated from the ovary. All mated females ligated 4 or 5 days after feeding developed their ova, but only 10% of ticks ligated 1 h after feeding did so. Thus, blood-feeding triggers the gradual release of a factor in the anterior region of the hemocoel which stimulates ovarian development. Ticks ligated 1–3 days after feeding showed intermediate values, indicating that the critical period for oocyte development is not narrowly defined in this tick. Oliver *et al.* (1992) arrived at a similar conclusion for *O. parkeri*.

Shanbaky and Khalil (1975) also tested the effect of injecting synganglion or hemolymph extracts (taken 1 h or 3 days after feeding) into the posterior compartment of ligated, mated females. Extracts of synganglion or hemolymph (3 days) stimulated oocyte development. Unfed, normal females did not respond to synganglion extracts, thus emphasizing the necessity of a blood meal for egg development in *A. arboreus*. In contrast, Chinzei *et al.* (1989a) and Taylor *et al.* (1991a) showed that egg development in *O. moubata* can occur in the absence of a blood meal.

Shanbaky *et al.* (1990b) monitored hemolymph vitellogenin (Vg) titer following injection of synganglion extracts into ligated female *Argas hermanni*. Normal vitellogenesis occurred even anterior to the ligature, indicating that the ovary itself does not participate in Vg synthesis. No Vg appeared in the hemolymph posterior to the ligature. Synganglion extracts also stimulate vitellogenesis when injected into fed virgin or mated *O. parkeri*, with activity occurring in both the supra- and subesophageal ganglia (Oliver *et al*., 1992).

The foregoing studies show that the synganglion contains a "vitellogenesis inducing factor" (VIF), but do not prove the NSCs as its source. Pyrethroid insecticides trigger the release of neurohormones in insects (Orchard and Osborne, 1979; Orchard, 1980; Ruight, 1985). Chinzei *et al.* (1989a) and Taylor *et al.* (1991a) showed that pyrethroid insecticides such as cypermethrin induce vitellogenesis and yolk uptake (but not oviposition) in unfed, mated, or virgin *O. moubata*. Cypermethrin induces Vg synthesis even in fourth instar nymphs (Taylor *et al*., 1991a). Indeed, the hemolymph Vg titer in cypermethrin-treated nymphs was higher than in similarly treated adult females, which the authors attribute to the inability of the prospective ovarian tissue to take up Vg. Cypermethrin stimulated Vg synthesis only when injected into the anterior of ligated females, further implicating the synganglion as its target (Chinzei *et al*., 1992).

3.16.3.4.4.2. The vitellogenic hormone Chinzei and Yano (1985) demonstrated that, as in insects, the fat body is the major site of vitellogenesis in *O. moubata* (see **Chapter 3.9**). Since then, several laboratories have described the course of vitellogenesis in argasid ticks e.g., *O. moubata* (Chinzei *et al*., 1989b; Chinzei and Taylor, 1990) and *A. hermanni* (Shanbaky *et al*., 1990c).

Not surprisingly, JH and related compounds have been tested as putative vitellogenic hormones in ticks. The following observations come from only a selection of studies that support a role for JH in argasid tick reproduction:

- The insect JHs and a number of related agonists all stimulated a normal degree of oviposition in fed virgin *O. moubata* (Connat *et al*., 1983b)
- The winter reproductive diapause of *A. arboreus* can be broken by a JHA (Bassal and Roshdy, 1974)
- P2 suppresses oogenesis in *O. parkeri*, an effect that is partially reversed by JH treatment (Pound and Oliver, 1979); P2 likewise induces sterility in

A. persicus and *O. coriaceus* (Leahy and Booth, 1980).

The following, however, do not support a role for JH in argasid tick reproduction (see also Connat and Nepa, 1990; Chinzei and Taylor, 1994):

- Although unfed *O. moubata* can express a normal degree of vitellogenesis when treated with cypermethrin (see Section 3.16.3.4.4.1), treatment with JH (I, II, or III) or any of four JHAs was totally ineffective in stimulating egg development (Chinzei *et al.*, 1991). Results for *O. parkeri* were similar (Taylor *et al.*, 1991b)
- P1 and P2 did not inhibit oocyte development nor did it reduce the hemolymph Vg titer in *O. moubata* (Taylor *et al.*, 1992). At best, high doses of P2 reduced oviposition in the surviving ticks.

Resolving these disparate conclusions will be no easy matter. Kaufman (1997) concluded:

> The only way [out] is to assume that JH acts on some system which becomes competent only following feeding, or that the primary role of JH in argasids is to stimulate oviposition only.

It can be seen below (Section 3.16.3.4.5.2) that studies with JH on ixodid ticks lead to similar discrepancies.

3.16.3.4.4.3. A model for hormonal control of egg production in argasid ticks VIF, a peptide from the synganglion, triggers vitellogenesis (see Section 3.16.3.4.4.1). Chinzei and Taylor (1990) showed that VIF acts somewhere in the posterior of the tick to produce a "fat body-stimulating factor," which in turn stimulates the fat body to synthesize and release Vg. The posterior compartment of ligated *O. moubata* can produce Vg if ligated 1 h after detachment, but in the anterior compartment does not produce Vg unless ligated 3 days after detachment. Thus, within an hour of detachment, VIF is present throughout the hemolymph. The fact that Vg appears in the posterior but not in the anterior compartment under these conditions indicates that an essential factor, produced by a tissue in the opisthosoma under stimulation by VIF, is required for vitellogenesis. Chinzei and Taylor (1994) and Taylor *et al.* (2000) speculate that the fat body-stimulating factor might be an ecdysteroid, because E and 20E increase Vg titer in the hemolymph of unfed mated females. Moreover, in mated *O. moubata*, there are peaks in the whole body and hemolymph ecdysteroid titer that correlate well with vitellogenesis and oviposition; in virgins, the ecdysteroid titer remains low throughout the 20-day postengorgement period (Ogihara, 2003). All this is in harmony with what is known for ixodid ticks (see Section 3.16.3.4.5.3). One potential problem with Chinzei and Taylor's (1994) model is that cypermethrin should not stimulate vitellogenesis if injected into either the anterior or posterior compartment of a ligated tick, as the posterior compartment lacks the synganglion, and the anterior compartment lacks the tissue source of a fat body-stimulating factor. And yet, Chinzei *et al.* (1992) reported that cypermethrin stimulated Vg synthesis when injected into the anterior compartment. To our knowledge, this anomaly has not yet been resolved.

3.16.3.4.5. Arachnida: Acari: ticks: family Ixodidae

3.16.3.4.5.1. Vitellogenin synthesis The fat body and some midgut cells are two major sites of Vg synthesis in *Dermacentor variabilis* and *Rhipicephalus appendiculatus* (Coons *et al.*, 1982, 1986, 1989; Rosell and Coons, 1990). In *D. variabilis*, synthesis of Vg begins early in feeding and the hemolymph Vg titer attains 430 μg ml^{-1} hemolymph when oviposition is under way (Rosell and Coons, 1991). The Vg concentration in the hemolymph of *Amblyomma hebraeum* peaks at almost 100 times this value (Friesen and Kaufman, 2002), a difference for which no firm explanation is available.

Recall that vitellogenesis in argasid ticks is triggered by a neuropeptide (VIF) (see Section 3.16.3.4.4.3). Oliver and Dotson (1993) state that fat body from fed virgin *H. dromedarii* increases Vg synthesis *in vitro* when exposed to synganglion extracts or to hemolymph from engorged females 2 days post detachment; this suggests that ixodids also use a neuropeptide to trigger vitellogenesis. Friesen and Kaufman (2003) tested this hypothesis by attempting to stimulate vitellogenesis in partially fed *A. hebraeum* using cypermethrin. Unlike what occurs in argasid ticks (see Section 3.16.3.4.4.1), however, cypermethrin failed to stimulate vitellogenesis at sublethal doses. Nevertheless, the strongest support for a neuropeptide triggering vitellogenesis in an ixodid tick comes from Lomas *et al.* (1997), who demonstrated that integument of adult female *A. hebraeum* does not synthesize ecdysteroids *in vitro* unless exposed to a neuropeptide (see Section 3.16.3.3.6); strong evidence that the vitellogenic hormone in ixodid ticks is an ecdysteroid is presented below (see Section 3.16.3.4.5.3).

Lunke and Kaufman (1993) demonstrated hormonal control of vitellogenesis by transplanting pieces of ovary into the hemocoels of engorged

females undergoing active vitellogenesis. The oocytes of those explanted ovaries which survived for 8 days were at an advanced stage of development. It is convenient to consider JH and ecdysteroids separately as the putative vitellogenic hormone.

3.16.3.4.5.2. Juvenile hormone and reproduction The earliest suggestions that JH might control vitellogenesis in ixodid ticks came from studies in which JH, JHAs, and precocenes were used to inhibit egg development. In most cases, however, the effects of these hormones and drugs may have been the result of nonspecific toxicity (Bassal, 1974; Mansingh and Rawlins, 1977; Hafez and Bassal, 1980; Leahy and Booth, 1980; Dees *et al.*, 1982; Gaber *et al.*, 1983; Khalil *et al.*, 1983, 1984; Connat, 1988; Slusser and Sonenshine, 1992). Alternatively, Hayes and Oliver (1981) fumigated eggs of *D. variabilis* with P2. This treatment caused a reduction in female-to-male ratio (from 1.1 : 1.0 for control versus 0.5 : 1.0 for P2), and an 85% reduction in the number of females completing the gonotrophic cycle. Such females treated with 1 μg JH III, 24 h prior to feeding (plus another 1 μg 6 days later) all completed the gonotrophic cycle, suggesting that P2 may have a specific anti-JH effect in this species. Moreover, the existence of a JH-binding protein (Kulcsár *et al.*, 1989) and JH esterase (Roe *et al.*, 1993) in ixodid ticks constitutes at least circumstantial evidence for JH. Finally, as mentioned above (see Section 3.16.3.3.6.2), hexane extracts of vitellogenic *B. microplus* possessed JH bioactivity, and hemolymph extracts from such females were recognized by antisera created against JH I, JH II, and JH III. But, similar to the findings of Neese *et al.* (2000), no JH 0, JH I, JH II, JH III, or MF were detected in the extracts by GC–MS (Connat *et al.*, 1987).

The following studies, however, diminish support that JH is the vitellogenic hormone:

1. Lunke and Kaufman (1993) could not induce egg development in partially fed female *A. hebraeum* by injections of JH, JHB_3, or MF. Nor could they inhibit egg development in fully engorged mated females by injections of precocene.
2. Methoprene does not stimulate the fat body of *D. variabilis* to synthesizes Vg *in vitro* (Sankhon *et al.*, 1999). Likewise, neither JH III nor triiodothyronine (a JH mimic in *Rhodnius*) (Davey and Gordon, 1996; Kim *et al.*, 1999) stimulated vitellogenesis when injected into partially fed *A. hebraeum* (Friesen and Kaufman, 2004).

In brief, the balance of evidence indicates that JH is not the vitellogenic hormone, but the nature of the substance in tick extracts having JH-like activity (Connat *et al.*, 1987), and what its role in reproduction might be, have not been adequately explained.

3.16.3.4.5.3. Effect of ecdysteroids on vitellogenesis There is reasonably firm evidence, however, that ecdysteroids regulate vitellogenesis in ixodid ticks:

1. The hemolymph ecdysteroid titer rises 10–100-fold during the first week postengorgement in female *A. hebraeum* (Connat *et al.*, 1985; Kaufman, 1991a; Friesen and Kaufman, 2002), coincident with maximum Vg synthesis. A similar profile occurs in *B. microplus*, although in this species, the peak ecdysteroid titer (70 ng ml^{-1}) is only about 12% that of *A. hebraeum* (600 ng ml^{-1}) (Connat *et al.*, 1986).
2. Ecdysteroids trigger SG degeneration within 4 days following engorgement (see Section 3.16.3.5.2), but hemolymph ecdysteroid levels continue to rise steeply for several days. The hormone titer peaks (at about five- to tenfold higher than the concentration necessary for SG degeneration) when Vg synthesis is most rapid (Kaufman, 1991a; Rosell and Coons, 1991; Lunke and Kaufman, 1993; Mao and Kaufman, 1999; Friesen and Kaufman, 2002).
3. James *et al.* (1997) monitored Vg synthetic activity of fat body *in vitro* and ecdysteroid content in whole body extracts of *I. scapularis* throughout the feeding and reproductive period. The observed rise and fall in ecdysteroid content, 1–2 days before the rise and fall of Vg synthetic activity in the fat body, is the pattern to be expected if vitellogenesis is controlled by an ecdysteroid.
4. 20E stimulates Vg synthesis by fat body of *D. variabilis* cultured *in vitro*; whereas the JH mimic methoprene had no such effect (Sankhon *et al.*, 1999). Friesen and Kaufman (2002) demonstrated that a physiological dose of 20E likewise triggers Vg synthesis in partially fed *A. hebraeum*, whereas JH does not.

Notwithstanding the strong evidence that an ecdysteroid serves as the vitellogenic hormone in ixodid ticks, why 20E is incapable of stimulating yolk uptake in partially fed ticks remains a puzzle. For example, Lunke and Kaufman (1993) infused 20E into partially fed females such that a high titer was maintained in the hemolymph over 24 h. Although the fat body became swollen (interpreted as a sign of active vitellogenesis), the oocytes did

not take up yolk. Treating engorged females with 20E (or 20E plus JH) did not hasten ovarian development compared to controls (Lunke and Kaufman, 1993). Although Friesen and Kaufman (2002) demonstrated that injected 20E stimulates Vg synthesis and release into the hemolymph, they confirmed Lunke and Kaufman's (1993) observation that oocyte development does not then follow. JH induces patency in the follicular epithelium of *Rhodnius* (Davey and Gordon, 1996), thus allowing the yolk direct access to the oocyte. Recall, however, that in chelicerates the eggs are not enveloped in a follicular epithelium (see Section 3.16.3.4.2), so there is unlikely to be a permeability barrier equivalent to the follicular epithelium that inhibits yolk uptake. Friesen and Kaufman (2004) considered the possibility that a Vg receptor may be downregulated in partially fed ticks. However, they identified an 86 kDa protein in the ovary as a putative Vg receptor, and found that it was present in partially fed females by the time they weighed 100 mg. Because 20E does not stimulate Vg uptake in ticks weighing 100–250 mg, downregulation of the Vg receptor also does not explain the inability of 20E to stimulate oocyte development. However, oocytes from partially fed females do take up yolk when ovaries are transplanted to the hemocoel of engorged females (Lunke and Kaufman, 1993). Taken together, all this suggests that some factor in engorged female hemolymph, distinct from the vitellogenic hormone, regulates yolk uptake.

The avermectins are broad-spectrum antiparasitic compounds that inhibit oviposition in ticks (Kaufman *et al.*, 1986). The avermectin analog MK-243 causes a marked reduction in hemolymph ecdysteroid titer and marked inhibition of ovarian development in engorged female *A. hebraeum* (Lunke and Kaufman, 1992). But whether MK-243 acts primarily by inhibiting ecdysteroid synthesis, Vg synthesis, or Vg uptake could not be determined until an enzyme-linked immunosorbent assay (ELISA) for Vg was available. Friesen *et al.* (2003) demonstrated that MK-243 did not significantly inhibit hemolymph Vg titer, and injections of 20E into MK-243-treated ticks did not restore measures of ovarian development. MK-243 may thus exert its major effect by inhibiting yolk uptake by the oocyte.

3.16.3.4.5.4. Hormonal control of spermatogenesis in ticks Hormonal control of spermatogenesis was reviewed by Oliver and Dotson (1993). Zhang *et al.* (1995) measured ecdysteroid content in extracts of fourth instar male *O. parkeri* nymphs throughout feeding and molting to the adult. There were two peaks of ecdysteroid, the first about 2 weeks after feeding (106 pg per tick; coincident with the late prophase of meiotic division I) and the second during the third week after feeding (277 pg per tick; coincident with epicuticle deposition). The later peak is undoubtedly associated with molting (ecdysis occurs around day 24–25). However, the authors suggest a role for 20E in spermatogenesis as well because (1) the earlier peak of ecdysteroid correlates with a key point in spermatogenesis and is not seen in female nymphs (Zhang *et al.*, 1995) and (2) 20E stimulates DNA synthesis in germ cells of unfed, male *D. variabilis* (Oliver, 1986).

3.16.3.5. Salivary Gland Development and Degeneration in Female Ixodid Ticks

Female ticks of the family Ixodidae feed to ~100 times their unfed weight (males barely double their weight during feeding). The meal is imbibed in two phases. During the slow phase (~7–10 days in *A. hebraeum*), tick weight increases ~10-fold; during the rapid phase (~1 day), tick weight increases a further tenfold.

3.16.3.5.1. Salivary gland development The SGs of unfed females secrete fluid *in vitro* very slowly (~4 nl min^{-1} in *Dermacentor andersoni*), but by the rapid phase of engorgement, the glands secrete at 217 nl min^{-1} (Kaufman, 1976). Coons and Kaufman (1988) transplanted SGs of unfed females into the hemocoels of partially fed females, and after several more days of feeding, ultrastructural changes characteristic of SG development were induced in the transplanted glands. Male SGs normally undergo much less development during feeding compared to female glands. When transplanted into the hemocoels of feeding females, however, development was similar to that of transplanted female glands. Thus, SG development in females seems to be controlled by a yet to be characterized humoral factor. It is interesting that the male SG seems to respond to a hormone that it normally would never encounter.

3.16.3.5.2. Salivary gland degeneration Following engorgement, the SGs undergo autolysis. Transplanting SGs from partially fed specimens to the hemocoels of engorged, but not partially fed, females induces SG degeneration in the transplanted tissue (Harris and Kaufman, 1981). Thus, SG degeneration is controlled by a hormone which Harris and Kaufman (1985) demonstrated to be an ecdysteroid. This hormone is released when females exceed a critical weight of approximately 10 times the unfed weight (Harris and Kaufman, 1984). Sensory

information from nerves in the opisthosoma is part of the pathway for the release of ecdysteroid (Harris and Kaufman, 1984).

Several studies indicate that the tick SG ecdysteroid receptor (EcR) is similar in many respects to the EcR of insects:

1. Only steroids that possess the structural requirements for ecdysteroid activity in insect systems (Horn and Bergamasco, 1985) (see **Chapter 3.3**) also trigger degeneration in tick SGs (Lindsay and Kaufman, 1988; Kaufman, 1991b).
2. Scatchard analysis of ^{3}H-ponasterone A binding to a cytosolic fraction of SGs from large partially fed ticks indicated a K_d and B_{max} of 0.72 nM and 175 fmol mg^{-1} protein, respectively (Mao *et al.*, 1995). Only steroids that meet the Horn and Bergamasco (1985) requirements are able to compete effectively for ponasterone A binding (Mao *et al.*, 1995).
3. Binding of the SG EcR of *A. hebraeum* (AheEcR) to *Drosophila* heatshock protein (hsp)27 EcR response element (EcRE) depends on heterodimerization with an ultraspiracle (USP)-like protein (see **Chapter 3.5**), and biologically effective ecdysteroids enhance this binding. Monoclonal antibodies against *Drosophila* EcR and USP reveal the tick equivalents on Western blots. Three bands react with the EcR antibody and, at any given time, between two to five react with the USP antibody (Mao and Kaufman, 1999). The hsp27 EcRE binding complex is shifted (gel mobility shift assay) by the *Drosophila* monoclonal antibody against USP (Mao and Kaufman, 1998).
4. Guo *et al.* (1997) isolated cDNAs from *Amblyomma americanum* that encode three EcR isoforms (AamEcRs) which have common DNA- and ligand-binding domains, but distinct amino termini that lack the F domain of insect EcRs. The common domains are 86 and 64% identical to the DNA- and ligand-binding domains, respectively, of insect EcRs. Guo *et al.* (1998) also isolated cDNAs encoding two retinoid X receptor (RXR) isoforms (AamRXR1 and AamRXR2), the DNA-binding domains sharing 95 and 87% identity with DNA-binding domains of insect USP and vertebrate RXR. The ligand-binding domains, however, share greater similarity with the vertebrate RXR (71%) than insect USP (52%). A functional receptor emerged when a monkey kidney cell line (containing luciferase reporter constructs and natural EcREs from *Drosophila*) was cotransfected with AamEcRA1 and either AamRXR1 or hRXR, and stimulated with muristerone A (Guo *et al.*, 1997).
5. Mao and Kaufman (1999), using Western blot analysis with *Drosophila* monoclonal antibodies, demonstrated the ontogeny of AheEcR and the USP-like protein throughout the feeding and reproductive period. EcR and USP-like protein were not detectable in the glands of unfed ticks. Three EcR bands and up to five USP bands were upregulated during the feeding period, reaching maximum density during the rapid phase of engorgement, and then falling away as the glands degenerated during the postengorgement period. This profile of upregulation correlated well with the peak hemolymph ecdysteroid titer during the rapid phase of feeding and, as mentioned above, exogenous 20E enhances the binding between the EcR/USP and hsp27 EcRE. Taken together, it appears that SG degeneration is triggered by ecdysteroid produced during the feeding period, and that 20E also upregulates the components of the functional receptor.

A *sine qua non* for identifying a hormone is that the putative substance must appear prior to the biological action it regulates. For the SGs of *A. hebraeum* to degenerate in culture, they must be exposed to a minimum of ~30 ng 20E ml^{-1}, and complete degeneration requires 100–150 ng 20E ml^{-1} (Harris and Kaufman, 1985). SG degeneration in normal engorged females is well under way within 1–2 days postengorgement (Harris and Kaufman, 1984), a time at which hemolymph ecdysteroid titers are below 20 ng 20E ml^{-1} (Kaufman, 1991a; Lomas and Kaufman, 1992b; Mao and Kaufman, 1999). Lomas *et al.* (1998) attempted to reconcile these disparities. One explanation may be that the glands require only 12 h (Harris and Kaufman, 1985) or 24 h (Lomas *et al.*, 1998) exposure to 20E, after which degeneration will proceed in its absence. Mao and Kaufman (1999) demonstrated a peak of hemolymph ecdysteroid (~50 ng 20E ml^{-1}) during the rapid phase of engorgement, after which the level fell back again to 20 ng 20E ml^{-1} during the first 2 days of postengorgement. It is possible that this peak during the rapid phase of engorgement constitutes the trigger for SG degeneration. Another possibility is that the SGs sequester ecdysteroid, such that the ecdysteroid concentration within the tissue is above the threshold for SG degeneration even though it is below that threshold in the hemolymph. Lomas *et al.* (1998) provide some evidence in support of this explanation.

Kaufman (1990) tested the effect of 20E on male SGs held in organ culture. Although 1 μg 20E ml^{-1}

induced a significant loss of fluid secretory competence, for reasons discussed in the paper, it was not possible to interpret this as SG degeneration.

3.16.3.6. A Role for 20-Hydroxyecdysone as a Reproductive Pheromone in Ixodid Ticks

The full repertoire of mating behavior in ticks is coordinated by a series of pheromones (Sonenshine, 1991). The three pheromones identified so far in ixodid ticks are (1) a volatile "attractive sex pheromone," which attracts males from some distance, (2) a "mounting sex pheromone," which induces the male to assume the copulatory position, and (3) a "genital sex pheromone," a nonvolatile secretion of the female genital tract which, when the male probes the female gonopore with his mouthparts, stimulates the male to produce the spermatophore and transfer it to the female. The first two pheromones are heterospecific, but only conspecific males respond to the third. 20E is reported to enhance the secretion of 2,6-dichlorophenol, the mounting sex pheromone of *Haemaphysalis longicornis* (Hai-Poong and Da-Xiang, 1999) and Taylor *et al.* (1991c) demonstrated that 20E is an important component of the genital sex pheromone, although presumably it is not the component that determines conspecific mating.

3.16.3.7. The Role of "Mating Factors" in Tick Reproduction

The sperm in any organism comprises the gametes plus secretions from various male accessory glands. Some of these male accessory gland secretions enhance fecundity and inhibit receptivity; often these are the same material in a given species (review: Gillott, 2003). A fecundity-enhancing substance is one that increases egg production, oviposition, or egg fertility. A receptivity-inhibiting substance is one that renders the female less likely to copulate with further males, and hence reduces their chances for paternity. Because such substances are produced by one individual in order to influence the physiology of another, strictly speaking they fall into the category of pheromones rather than hormones. Nevertheless, these mating factors merit a brief mention here because of their influence on reproductive endocrinology.

Although male ticks appear not to transfer a receptivity inhibiting substance to the female (relying instead on proximate mate-guarding for assuring paternity), a number of mating factors have been identified in ticks which enhance fecundity (review: Kaufman, 2004), as summarized below.

3.16.3.7.1. A "sperm capacitation factor" from argasid and ixodid ticks Spermatozoa must undergo capacitation before they are capable of fertilizing eggs. In both argasid and ixodid ticks, a 12.5 kDa protein originating from the male accessory gland stimulates capacitation following transfer to the female (Shepherd *et al.*, 1982). The sperm capacitation factor from argasid ticks is not active on the sperm of ixodid ticks and vice versa.

3.16.3.7.2. A "vitellogenesis-stimulating factor" from argasid ticks When virgin *O. moubata* feed, they begin vitellogenesis but then resorb the yolk within 3 months (abortive vitellogenesis) (Connat *et al.*, 1986). If mated at this time, vitellogenesis resumes and oviposition occurs, an effect caused by a "vitellogenesis-stimulating factor" (VSF). One or two large proteins (100 and 200 kDa), originating from within the spermatozoon itself, constitute VSF (Sahli *et al.*, 1985). Whether VSF acts directly on the fat body to stimulate Vg synthesis or on the neuroendocrine system is not known.

3.16.3.7.3. A "male factor" from ixodid ticks SG degeneration occurs in *A. hebraeum* which have exceeded the critical weight, a process regulated by 20E (see Section 3.16.3.5). Whereas the process takes only 4 days in mated females, it takes 8 days in virgins (Lomas and Kaufman, 1992a). This difference is due to a protein (20–100 kDa) from the testis/vas deferens, and is responsible for a number of other physiological and behavioral changes in the female which enhance fecundity (Kaufman and Lomas, 1996).
